The PG-3 group of genes seemed to have no corresponding gene in *Drosophila*. However, analysis of HOX cluster genes in other arthropods suggests that the *Drosophila* genes *zen* and *zen2* are the homologs of the PG-3 genes, and that they diverged substantially in flies. They have taken on novel roles during development, that is, dorsal–ventral patterning, rather than anterior–posterior patterning. Another *Drosophila* gene not involved in anterior–posterior patterning is *bicoid* (*bcd*). *bcd* is the most divergent gene in the *Drosophila* HOX cluster (Fig. 3). Its functional role is as a maternal morphogen in the early *Drosophila* embryo, where the protein forms a gradient in the egg. Recent evidence indicates that *bcd* has arisen by a duplication from a PG-3 gene during insect evolution and has undergone rapid sequence divergence as an adaptation to its novel function.

2.1.4 **Deformed (Dfd) Family**

This family comprises the *Drosophila Deformed* gene and the vertebrate PG-4 group genes. This family also has small

Fig. 5 Examples of homeodomain sequences of different groups. Only the homeodomain sequences are shown and flanking sequences have been omitted. The homeodomain sequences have been grouped on the basis of classes and families, and major groups have been boxed and labeled on the right. In the case of the SATB class sequence, one residue has been removed in the loop between helix 1 and 2 to maintain alignment. In this figure and all subsequent sequence alignments, the following conventions apply: A consensus (based on the most frequently encountered amino acid at a particular position) is shown at the top and dots indicate identities to the consensus. Dashes indicate a gap introduced for optimal alignment. Where sequences are incomplete or unavailable, empty spaces have been left; an asterisk (*) marks a stop codon. Some of the species codes used in this and subsequent figures are d, *D. melanogaster*; Ce, *C. elegans*; m, mouse; r, rat; c, chicken; h, human; zf, zebra fish; x, *Xenopus laevis*.

Fig. 5 (*Continued*)

and PG-8, and the *C. elegans* gene *mab-5*. The homeodomains of this family are extremely conserved between flies and vertebrates (up to 98%). It seems likely that there existed only one common ancestral gene and that independent duplication events gave rise to the PG-6, PG-7, and PG-8 group genes in vertebrates and to the *Antp*, *Ubx*, *abd-A*, and *ftz* genes in flies. The *Drosophila ftz* gene is not involved in axial patterning, but functions in segmentation. A very cryptic Hexapeptide can be found upstream of the homeodomain, but in other insects and in arthropods, the

Fig. 5 (*Continued*)

orthologous gene is better conserved, and in some species, it still seems to play a role in pattern formation.

2.1.7 Abdominal-B (Abd-B) Family

The Abd-B family of genes is located at the 5′ end of the cluster. They are more divergent than other cluster genes and they do not encode a Hexapeptide. While *Drosophila* has only one gene, *Abd-B*, there are five paralogue groups, PG-9 to PG-13, in vertebrates. The Abd-B homeodomain is 52 to 75% identical to the various human and mouse Abd-B family homeodomains; thus, these genes can be very divergent. The further removed from the center of the HOX cluster the paralogue groups are, the more divergent their homeodomain sequences become. *HoxD-9* to *HoxD-13* play important roles during pattern formation of limbs in vertebrates. In *C. elegans,* the homeodomain of PHP-3 is most similar to Abd-B (82% identical),

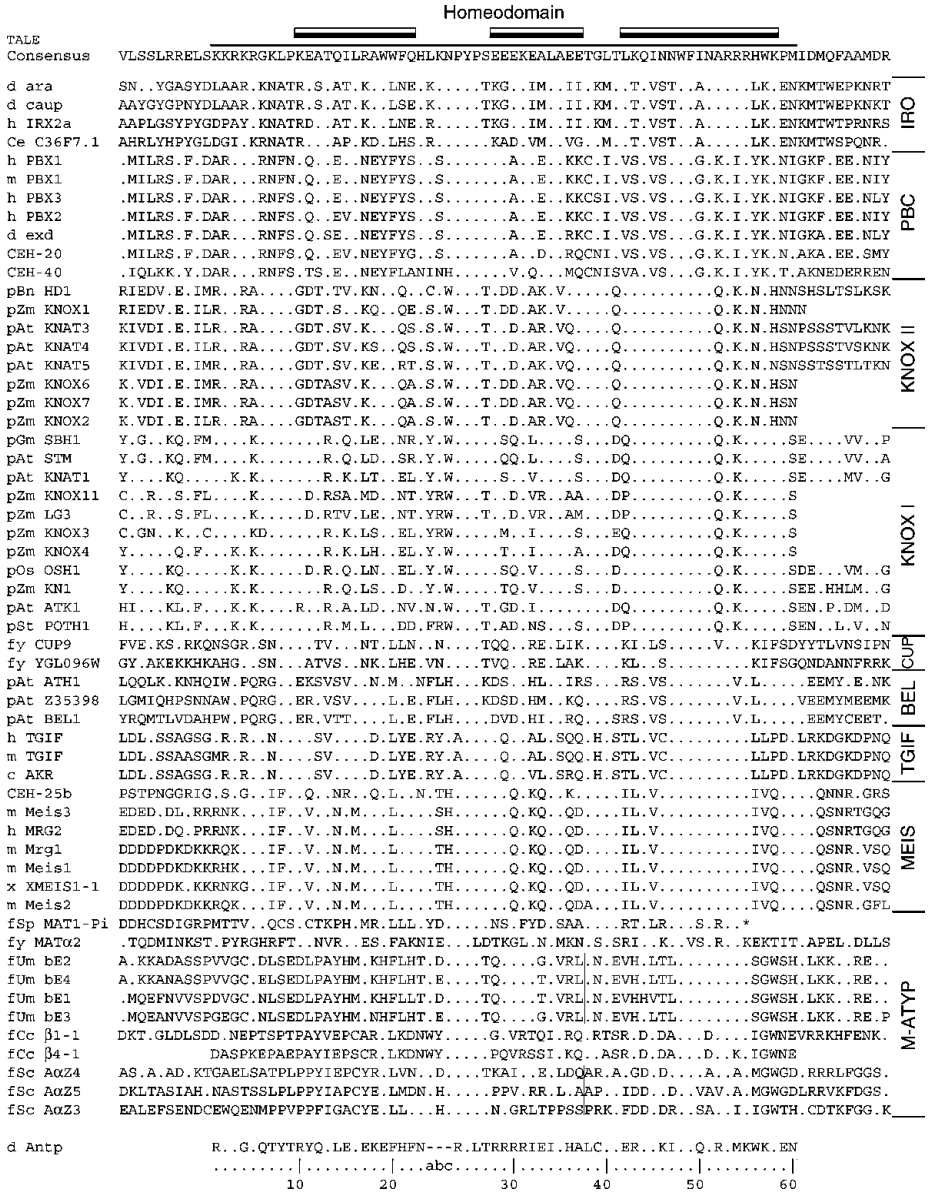

Fig. 6 Examples of TALE homeodomain sequences. At the top, the three α-helices of the homeodomain and a consensus derived from 58 TALE sequences are shown. On the right, the different TALE classes from animals, fungi, and plants are indicated. The fly Antp homeodomain sequence is shown at the bottom for comparison. Plant genes are denoted by a ''p'' and fungal genes are denoted by an ''f'' in front of their species code, respectively. The thin line in the loop region between helix 2 and helix 3 in the fungal genes from *Ustilago maydis* (fUm) and *Schizophyllum commune* (fSc) indicates the region where extra residues were removed from the loop for this alignment.

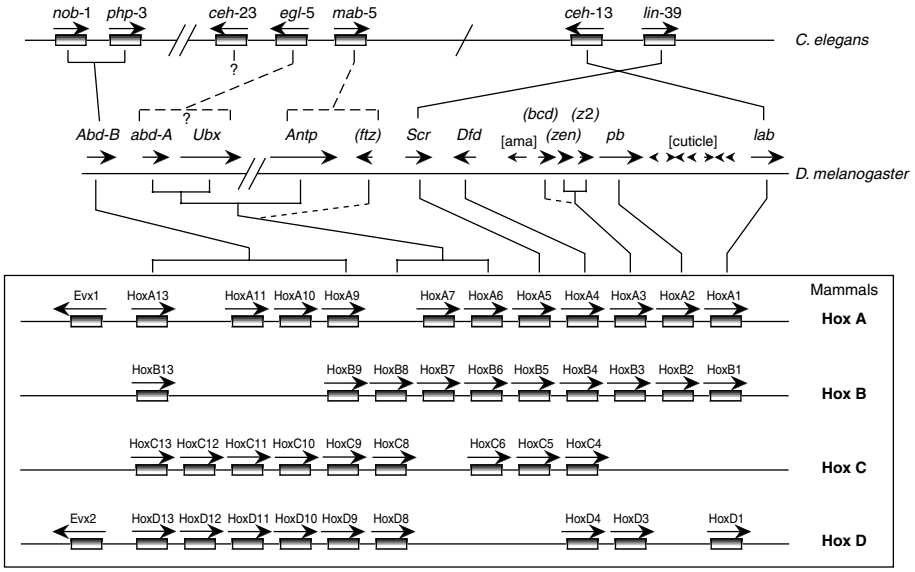

Fig. 7 Organization of the *C. elegans*, *D. melanogaster*, and mouse/human HOX clusters. At the top is a schematic representation of the *C. elegans* HOX cluster. The *Abd-B* genes (*php-3*, *nob-1*) have split far from the rest of the cluster. Of the remaining five genes in the cluster, only four genes can be assigned to fly/vertebrate homologs, in the case of *mab-5* and *egl-5*, only tentatively. The relationship of the homeobox gene *ceh-23* is unclear. In the center is a representation of the *D. melanogaster* HOX cluster, composed of the two complexes ANT-C (right) and the BX-C (left); large arrows indicate the individual transcription units of homeobox genes, while small arrows represent nonhomeobox genes (names in square brackets), and gene names of nonhomeotic homeobox genes are given in parentheses. At the bottom of the panel, the organization of the four mammalians – based on mouse and human-HOX clusters (HOXA, HOXB, HOXC, HOXD) is shown. The orientation of transcription is indicated by arrows. Black lines and brackets between the *C. elegans*, *D. melanogaster*, and mammalian clusters mark the homologous genes. Dashed lines indicate less certain sequence relationships or derived sequences.

while NOB-1 is only 52% identical, and EGL-5 53%. While *nob-1* is classified as an Abd-B gene, the assignment of *egl-5* is less certain, variously grouped either as Abd-B or as divergent Antp family gene (Fig. 7).

2.1.8 **Even-skipped (eve) Family**

The vertebrate eve genes (*Evx*) are located at the 5′ end of the HOX cluster (Fig. 7), suggesting that this gene family is part of the extended HOX cluster. In other organisms such as *Drosophila* and *C. elegans* though, the single eve family genes are not linked to the HOX cluster. Like the Abd-B family, the eve genes do not contain a Hexapeptide upstream of the homeodomain. Their homeodomain sequences are very different from the Antp and Abd-B family homeodomains, and in addition, the intron position is in a different location than in Hox genes. The original function of the eve family genes appears to be pattern formation in the posterior of the animal, which is consistent with its position in the HOX cluster. The eve family is very ancient since an *eve* gene has been isolated from corals, where it has

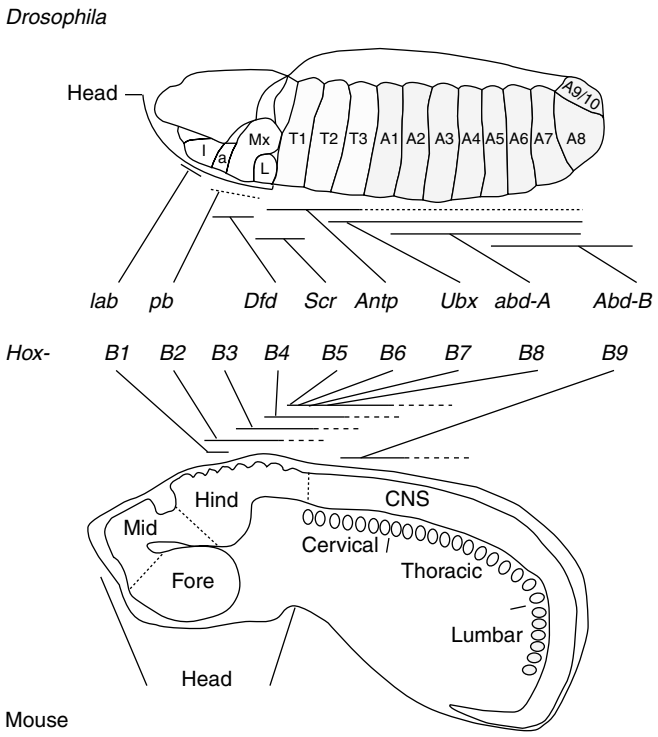

Fig. 8 Schematized domains of expression for the fruit fly HOX and the mouse HOXB cluster genes, as mapped onto a 10-h *Drosophila* embryo, or a mouse embryo at day 12, respectively. Bars indicate the approximate areas of expression for individual genes. Additional labels include I, a, Mx, L – intercalary, mandibular, maxillary, and labial segments of the presumptive head; T1–T3: thoracic segments; A1–A8: abdominal segments; Fore, Mid, Hind: forebrain, midbrain, and hindbrain; CNS: central nervous system. The labels cervical, thoracic, and lumbar indicate the somites of the respective body regions. Adapted from McGinnis, W., Krumlauf, R. (1992) Homeobox genes and axial patterning, *Cell* **68**, 283–302.

been found linked to a gene similar to HOX cluster genes.

2.1.9 **Mox Family**

The Mox genes were found to be linked to the HOX cluster in vertebrates, on the side of the anterior Hox genes, and thus belong to the extended HOX cluster. However, sequencewise, these genes are probably derived by duplication from the posterior genes, most likely from the eve family genes. The Mox family is conserved; a homolog, *buttonless*, has been found in *Drosophila*.

2.2 **ParaHox Cluster**

The ParaHox gene cluster is composed of three gene families, Gsx, Xlox, and cad (Fig. 10a). This cluster was first identified

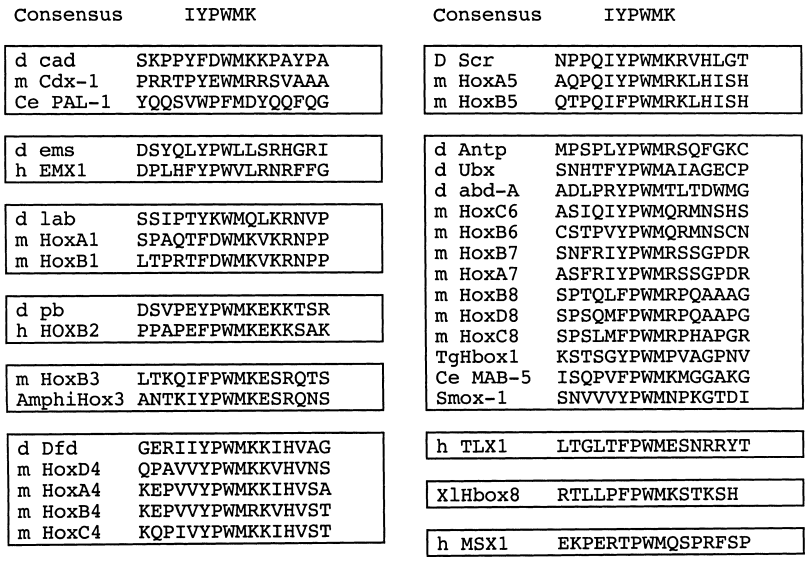

Fig. 9 Hexapeptide sequences. The top line shows a consensus sequence for the core of the Hexapeptide. Examples of Hexapeptide sequences from various families and classes are given.

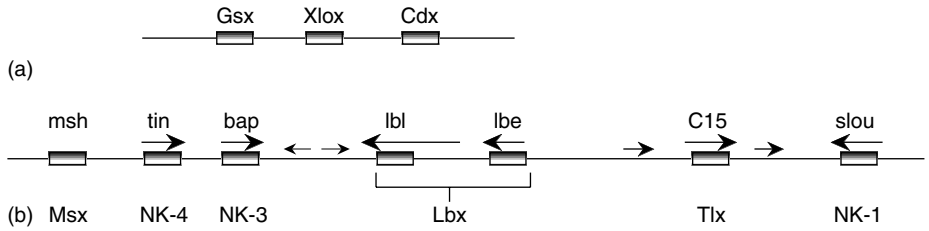

Fig. 10 (a) Schematized gene arrangement for the ParaHox gene cluster as found originally in Amphioxus. It is composed of three gene families Gsx, Xlox, and Cdx, Gsx corresponding to the most anterior and Cdx to the most posterior functioning gene. (b) Schematic representation of the NK gene cluster. This is a derived composite of the clusters found in mosquito (*Anopheles gambiae*) and *D. melanogaster*, respectively. In *Drosophila*, the *msh* gene is not linked to the cluster anymore, while in mosquito, the *NK-1* gene is not linked to the cluster anymore. Furthermore, there is only a single *Lbx* gene in mosquito.

in Amphioxus, but a cluster is also present in mammals. Nevertheless, this cluster is not as highly conserved as the HOX cluster. For instance, only one intact ParaHox cluster is found in mammals, while paralogous genes are no longer found in clusters. The *ParaHox* genes are very similar in sequence to the HOX cluster genes and they all encode a Hexapeptide upstream of the homeodomain (Fig. 9). It is thought that the ParaHox cluster probably arose through a duplication event from an ancestral HOX cluster. The ParaHox genes also function in anterior–posterior patterning, with the Gsx genes being the most anterior, and the cad genes being the most

posterior. An important functional aspect of the ParaHox cluster seems to be in the patterning of the endoderm.

2.2.1 **Gsx Family**

These genes were first isolated from mouse (*Gsh-1, Gsh-2*). On the basis of the homeodomain sequence, the Gsx and Xlox (see next section) proteins are very similar to the pb and PG-3 family of HOX cluster genes, confirming the notion that the ParaHox cluster arose through some duplication event of a ProtoHox cluster.

2.2.2 **Xlox Family**

The *Xenopus* gene *Xlhbox8* and several leech genes (*lox*) form the founding members of this family. In *Drosophila*, the *Xlox* gene seems to have been lost, while in *C. elegans* both *Xlox* and *Gsx* genes are lacking.

2.2.3 **Caudal (cad) Family**

The function in *Drosophila* and the expression patterns in vertebrates indicates that these genes are important in axial pattern formation in the posterior. Often, they play a role in the development of the endoderm. The *C. elegans* gene *pal-1*, while clearly a member of the cad family, does not have a readily recognizable Hexapeptide upstream of the homeodomain (Fig. 9).

2.3 **The NK Cluster**

The NK cluster was discovered in *Drosophila*, where a series of homeobox genes were found to be clustered in the chromosomal region 93DE (Fig. 10b), hence it is also referred to as the 93DE cluster in *Drosophila*. A corresponding cluster has also been identified in mosquito, although the gene arrangement has slightly changed since in mosquito, the NK-1 orthologue is separate from the cluster, while the Msx gene is still in the cluster (Fig. 10b). This cluster, however, has not been that well conserved in vertebrates, only fragments still exist and the genes have dispersed through the genome. A main function of the NK cluster genes is in pattern formation and development of the mesoderm.

2.3.1 **NK-1 Family**

The homeodomains of the NK-1 class have been highly conserved between flatworms, nematodes, flies, and vertebrates (Fig. 7). The fly gene *slouch* (*slou/NK-1/S59*) is orthologous to the vertebrate genes *Nkx-1.1* and *Nkx-1.2* (also known as *Sax*).

2.3.2 **Tlx Family**

The human gene *TLX1* (*TCL-3*) is one of the better-known cases of a homeobox-containing genes involved in cancer; in this case T-cell leukemia, and, thus, this gene family was named Tlx. The orthologous gene, *C*15, from *Drosophila* has not been studied well yet. The Tlx genes encode a Hexapeptide upstream of the homeodomain (Fig. 9).

2.3.3 **Lbx Family**

There are two Lbx family genes in *D. melanogaster, ladybird early* (*lbe*) and *ladybird late* (lbl). This seems to be a recent duplication from a single, ancestral *Lbx* gene since in *Anopheles* there is only a single *Lbx* gene. In vertebrates, the *Lbx* genes are still found linked to the *Tlx* genes; there are two paralogous miniclusters with *Lbx1* and *Tlx1*, and *Lbx2* and *Tlx2*, respectively.

2.3.4 NK-3 Family

This family is defined by the fly gene *bagpipe* (*bap*) and the vertebrate genes *Nkx-3.1* and *Nkx-3.2*.

2.3.5 NK-4 Family

This family is defined by the vertebrates genes *Nkx-2.3, Nkx-2.6*, and *Nkx-2.5* and the fly gene *tinman* (*tin*). Together with the NK-2 family, some of the NK-4 family genes share a conserved region (CP) downstream of the homeodomain (Fig. 4).

2.3.6 Msx Family

The Msx family of genes were first identified in vertebrates (as *Hox-7* genes) and in flies a corresponding gene, *msh* (*muscle-specific-homeobox*), was identified. The vertebrate genes were renamed as *Msx* genes because they were not part of the HOX cluster. The Msx family is very ancient since a member has been cloned from hydra. The sequence conservation extends outside of the homeodomain; there are at least eight amino acids immediately upstream of the homeodomain and five amino acids immediately downstream that are conserved between hydra and vertebrate Msx proteins. Also, a cryptic Hexapeptide is found in some of the genes (Fig. 9).

2.4 Noncluster Antennapedia Superclass Genes

A large group of Antp superclass gene families that are conserved from protostomes to deuterostomes are dispersed through the genome and are not, or no longer, organized in clusters. Many of them, such as NK-2, Dll, and ems, are similar to genes in the NK cluster and are loosely grouped into the NKL class.

2.4.1 NK-2 Family

The NK-2 family of homeobox genes is defined by the fly homeobox gene *NK-2* (now known as *ventral nervous system defective, vnd*). The first vertebrate gene of this family to be isolated was the transcription factor *TTF-1*. The vertebrate genes are now called *Nkx-2.1* and *Nkx-2.2*. Several of the fly and vertebrate proteins share a small conserved sequence element of about 17 amino acids downstream of the homeodomain, referred to as the *conserved peptide* (CP), or *NK2-SD* (Fig. 4). A small conserved region is also found near the amino terminus, referred to as *TN-domain*. The NK-2, NK-3, and NK-4 family of genes are closely related so that these genes were originally classified all within the NK-2 class. Thus, the vertebrate nomenclature that uses Nkx-2.x for genes that fall into separate families is confusing.

2.4.2 Distal-less (Dll) Family

Six *Dlx* genes are found in mammals, while only one fly and one nematode gene is known. The *Drosophila* gene has been shown to play an important role in limb development. In vertebrates, the *Dlx* genes are expressed in various areas of the brain, but intriguingly, some are also expressed in the limbs; thus, it is thought that *Dlx* genes play an important role in the formation of appendages.

2.4.3 Empty-spiracles (ems) Family

The genes of the ems family, though not part of any cluster, have a Hexapeptide upstream of the homeodomain. These genes function in pattern formation mainly in the head region. There are at least two genes in mammals and two in flies, which appear to have arisen from independent duplication events. In *C. elegans,* the ems family gene *ceh-2* plays a role in neuron specification in the anterior pharynx.

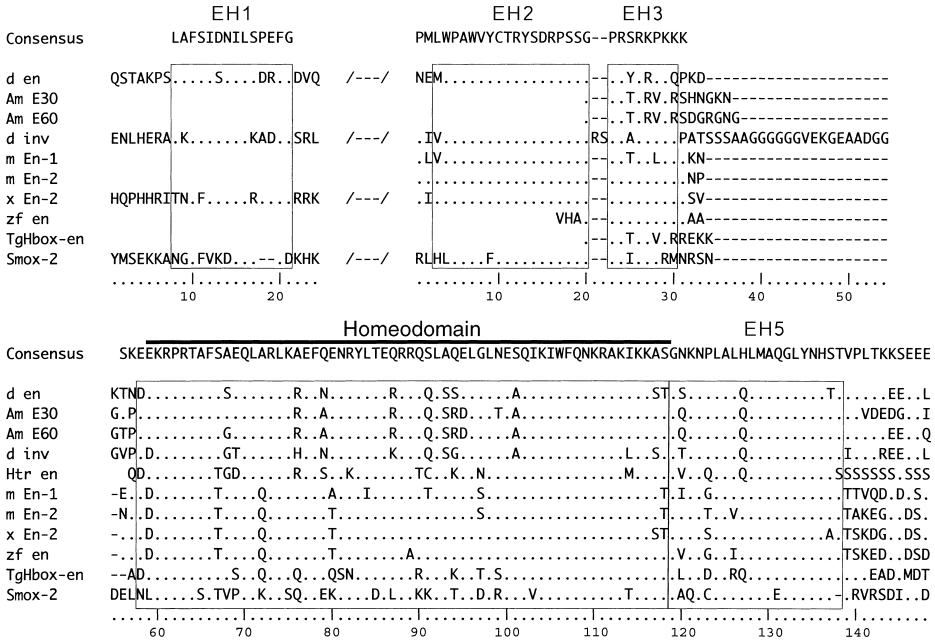

Fig. 11 Alignment of engrailed family sequences. The black bar denotes the homeodomain and the boxes indicate the domains that have been conserved between deuterostomes and protostomes. The slashes indicate a long nonconserved region of variable length. Two conserved regions can be found upstream of the homeodomain (EH1, and EH2/EH3) and a third region of conservation (EH5) is just downstream of the homeodomain, followed by a charged region.

2.4.4 Engrailed (en) Family

The engrailed family of genes is characterized by a series of small conserved motifs outside of the homeodomain (Fig. 11). These motifs were named EH1, EH2, EH3, EH4 (the homeodomain), and EH5. EH1 is a small conserved region (~13 amino acids) toward amino terminus of en family genes, EH2 and EH3 are adjacent conserved regions of about 20 and 8 amino acids just upstream of the homeodomain. EH2 contains residues that are somewhat reminiscent of the Hexapeptide. EH5 is a carboxy-terminal extension of the homeodomain of about 20 amino acids that is followed by a charged region. The current evidence suggests that one ancestral *engrailed* gene existed in the ancestor of vertebrates and arthropods and that, later, independent duplication events gave rise to *en* and *invected* (*inv*) in flies and *En-1* and *En-2* in vertebrates. The nematode *C. elegans* has only one en family gene, *ceh-16*.

2.4.5 Hlx Family

Genes similar to the *Drosophila* gene *H*2.0 have been isolated from vertebrates and ascidians. Chicken *Chlx-A* and mouse *Dbx* genes as well as the *Ascidia* gene Hal-*hlx* are quite different from *H*2.0 and the mouse *Hlx* gene; thus, this family seems to have evolved divergent members.

2.4.6 Hex Family

The first identified member was in mammals (Prh). This gene family is rather

distinct from Extended HOX cluster genes or NKL genes, although it is highly conserved down to cnidaria, suggesting an important role in animal development.

2.4.7 Other Families

A substantial number of additional families that have been conserved from protostomes to deuterostomes have been identified. Most of these families are similar to the NK cluster genes and can be loosely grouped into the NKL class of homeobox genes. These families include Bar, bsh, ceh19, Gbx, Gtx, Xnot, Mnx, NEC, and Vent, although the last family does not seem to be present in flies. The rough (ro) family is more similar to the ExHox class of genes. Other genes, such as the *C. elegans* genes *ceh-7* or *ceh-5*, are rather divergent from any of the other genes and no obvious homologs can be detected presently, suggesting that these genes diverged in the nematode lineage and are derived from some other homeobox gene. Similarly, other newly derived genes, as also the example of *bcd* shows, will exist only within particular animal phyla.

2.5 Antennapedia Superclass Related Genes in Lower Animals

Quite a number of homeobox genes have now been isolated from cnidaria, such as hydra or corals as well as sponges. Some are most closely related to the genes of the HOX, ParaHox, and NK cluster, as mentioned above. Others are clear orthologues of other Antp superclass genes, such as for example, en. An Antp-like gene has been isolated from coral, and this gene has been shown to be linked to an eve class gene. Thus, a primitive cluster does exist, but it may have dispersed more in lower organisms. Antp superclass homeobox genes have also been discovered in what is thought to be the most primitive animal, *Trichoplax adhaerens* (Placozoa). Once full genome projects are available, it will be possible to determine the full complement of homeobox genes and elucidate the evolutionary history of these genes.

3 Paired and prd-like Classes

3.1 Paired (prd) Class

The paired class of homeobox genes is characterized by the fact that their homeodomains contain a serine residue at position 50. In addition, a highly conserved domain of about 130 amino acids, the ''paired'' domain, is found toward the amino terminus of these proteins. prd class genes have been shown to be transcription factors, and the prd domain by itself has been shown to bind DNA. The structure has recently been determined and shown to consist of two globular domains with three α-helices each. Several genes have been found that encode only a prd domain but no homeodomain. In contrast, thus far, all homeodomain proteins of the prd class that contain a serine residue at position 50 also contain a prd domain. The prd domain bears resemblance to transposases, and it is thought that a prd-like homeobox gene captured a transposase early in metazoan evolution, which then evolved into the prd domain. In addition to the prd domain, the prd class genes show some extended sequence conservation just upstream of the homeodomain, and some families have an ''Octapeptide'' between the prd domain and the homeodomain (Fig. 4). Aligned

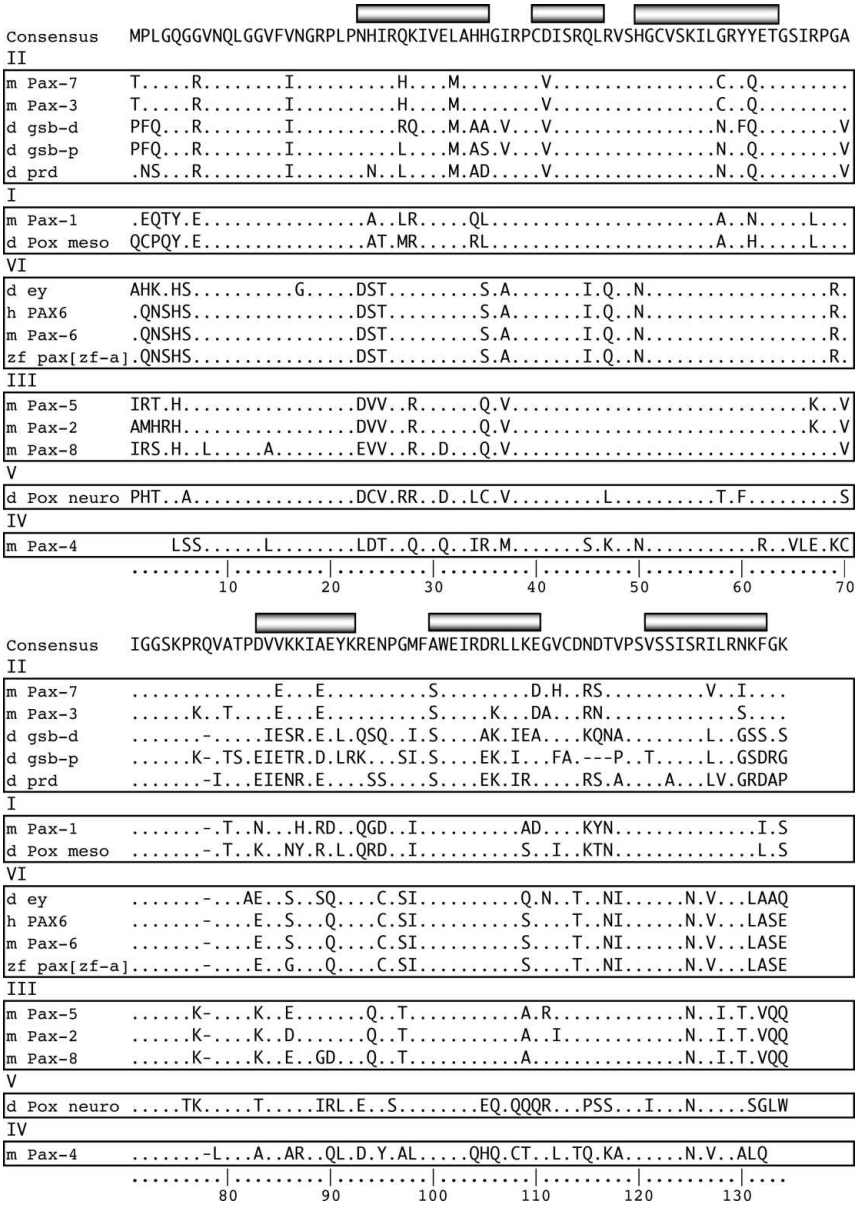

Fig. 12 Alignment of paired domain sequences. The sequences are grouped into six families (I–VI) and the family number is given above each group. The six helices of the two globular domains are indicated by cylinders. Helices 1, 2, and 3 form the first globular domain; helix 2 and 3 fold into a helix-turn-helix motif, and, similar to the homeodomain, the third helix sits in the major groove of the DNA. Helices 4, 5, and 6 form the second globular domain.

prd domains are shown in Fig. 12. The prd class genes can be grouped into six families on the basis of this domain. In vertebrates, prd class genes are called *Pax genes*, irrespective of whether they have a homeodomain or not.

3.1.1 **Family I**

The genes of this family, formed by mouse *Pax-1* and *Drosophila Pox meso*, do not encode homeodomains. A mutation in mouse *Pax-1* is responsible for the *undulated* defect.

3.1.2 **Family II**

This family includes the *Drosophila* genes *prd, gsb-d, gsb-p* and the mouse genes *Pax-3* and *Pax-7*. Apparently, independent duplication events gave rise to the multiple genes in vertebrates and flies. This family contains a small conserved region (the Octapeptide) between the homeodomain and the prd domain. In humans, a defect in *Pax-3* causes phenotypes known as the *Waardenburg syndrome* and *craniofacial-deafness-hand syndrome*. In mouse, a mutation is known as *Splotch*.

3.1.3 **Family III**

Presently, this family is defined only by vertebrate genes (*Pax-2, Pax-5, Pax-8*) and may be vertebrate specific. Interestingly, these genes encode a protein piece that resembles the first third of a homeodomain. This suggests that the last two thirds of the homeodomain was only recently lost in evolution. Like in family II, these genes also encode an Octapeptide between the prd domain and the homeodomain remnant. A mutation in the human *Pax-2* gene causes kidney and retinal problems.

3.1.4 **Family IV**

This family is defined solely by *Pax-4*. This family may be derived from *Pax-6* genes.

3.1.5 **Family V**

This family is defined by *Pox neuro*, which has no homeodomain.

3.1.6 **Family VI**

This family is well conserved in evolution, encompassing such genes as *Pax-6* in vertebrates and *eyeless* (*ey*) in flies, and they encode both a prd domain and a homeodomain. *Pax-6* is mutated in the *Small eye* mutations in mice and rats, and in the *Aniridia* mutation in humans; thus, *Pax-6* plays a crucial role in eye development. The fly gene *ey* was shown to be homologous to *Pax-6*. Thus, these genes play important roles for eye development both in vertebrates and flies, despite the large differences in eye structure and development between these phyla. This suggests that there is a common underlying mechanism for ''eye development'' that has been conserved in evolution and that vertebrate eyes and insect eyes are not completely independent inventions of evolution.

3.2 **Paired-like (prd-like) Class**

A substantial number of homeobox genes encode a homeodomain that is similar to the prd class homeodomains but they do not encode a paired domain nor do the homeodomain sequences have a serine residue at position 50. Some of these prd-like homeodomain sequences can be as much as 75% identical to prd class homeodomain sequences. Given that the prd class genes are thought to be derived from prd-like homeobox genes, this similarity is not surprising. In recent years an increasing number of conserved prd-like families has been identified. The following families have been conserved between different phyla:

otd/Otx (fly orthodenticle), ceh10, unc4, Arix/Phox, Ptx/unc30, al (fly aristaless), otp (orthopedia), Gsc (goosecoid). Several other families seem, at present, to only occur in vertebrates, suggesting a possible vertebrate-specific expansion. While most of the prd-like genes encode glutamine residues at position 50, several families (for example, *goosecoid, otd*) encode lysine residues at that position. A feature often found in prd-like class genes is the presence of an intron between amino acids 46 and 47 of the homeodomain. Some of the families have quite extensive sequence conservation outside of the homeodomain. For example, the ceh10 family has a motif of about 70 amino acids immediately downstream of the homeodomain that is conserved from *C. elegans* to vertebrates. Many of the prd-like class genes play important roles in the developing nervous system.

4 POU Class and HNF Classes

4.1 POU Class

The POU class was originally defined on the basis of the four genes *Pit-1*, *Oct-1, Oct-2*, and *unc-86* (POU). The POU-specific domain is an approximately 80-amino acid long conserved domain upstream of the homeodomain with a variable linker in between (Fig. 13). Several of the POU class genes were originally isolated as transcription factors, which provided the most convincing evidence that homeobox-containing genes encode transcription factors. The POU-specific domain is required for cooperative, high affinity DNA-binding and has so far always been found in association with a POU homeodomain. The POU homeodomain is characterized by a cysteine residue in position 50. The structure of the POU domain, that is, the POU-specific domain and the POU homeodomain, bound to DNA has been determined. The POU-specific domain consists of four α-helices (indicated in Fig. 13). Helix 2 and 3 fold like a helix-turn-helix motif, although the turn between Helix 2 and 3 in the POU-specific domain is larger than that in a standard helix-turn-helix protein (such as the homeodomain). The genes have been grouped into several families and many play important roles in nervous system development.

4.1.1 Family I

Represented by the gene *Pit-1* and only found in vertebrates so far.

4.1.2 Family II

Encompasses the well-known mammalian transcription factors *Oct-1* and *Oct-2*, and at least one additional member in vertebrates, *Oct-11*. The *Drosophila* genes of this family, *nubbin* (*pdm-1*) and *pdm-2* have arisen through independent duplication events in arthropods. A divergent member of this family is the *C. elegans* gene *ceh-18*.

4.1.3 Family III

Comprises at least four vertebrate members, that is, *Brn-1, Brn-2, SCIP/Oct-6*, and *Brn-4*, one in *Drosophila* (*vvl/Cf1a*), one in *C. elegans* (*ceh-6*), as well as two genes in flatworms.

4.1.4 Family IV

This family is highly conserved between vertebrates, flies, and nematodes. The *C. elegans* gene, *unc-86*, is expressed and functions in many neurons of the sensory nervous system.

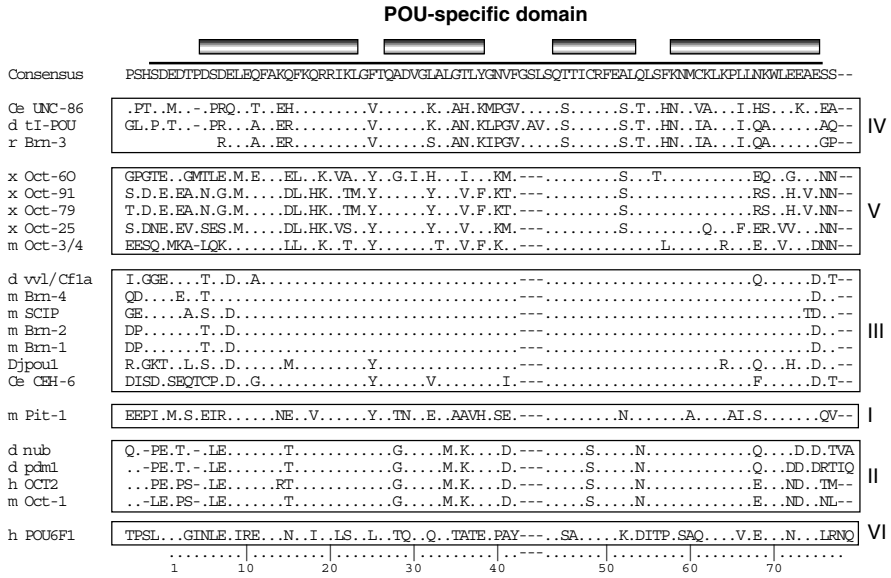

Fig. 13 Alignment of sequences for the POU-specific domain (marked by the black bar at the top). Examples of *POU* genes are given and grouped into different families (I–VI). The four shaded cylinders indicate the four α-helices of the secondary structure of the POU-specific domain. Helix 2 and 3 form a helix-turn-helix motif.

4.1.5 Family V

This group is a diverse assortment of genes, some of which can be quite divergent from each other. This family seems to be restricted to vertebrates.

4.1.6 Family VI

This family is conserved between flies and vertebrates but has been lost in *C. elegans*.

4.1.7 Orphans

Several additional POU genes in vertebrates exist (e.g. *Sprm-1*) that are very different from the above families and may represent novel derived genes in vertebrates.

4.2 HNF Class

The HNF class was originally defined by the mammalian transcription factor LFB1 or HNF1α. Figure 14 shows the homeodomain of HNF1α and the extra residues that are found between helix 2 and helix 3. The HNF class genes have been found to have a conserved domain upstream of the homeodomain (not shown). The structure of this domain has been determined and found to be similar to that of the POU domain, suggesting that the HNF class might be highly divergent and be derived from *POU* genes.

5 Cut Superclass

The first gene of this superclass discovered was the *Drosophila* homeobox gene *cut*, which has three copies of a conserved domain of about 80 amino acids, the cut domain (Fig. 15), upstream of the

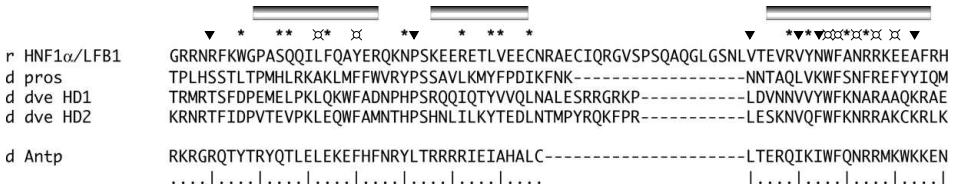

Fig. 14 Alignment of the atypical homeodomain sequences of rat HNF1α/LFB1, *D. prospero*, and the two homeodomains – marked by HD1 and HD2 – of *Drosophila* defective proventriculus (dve). Symbols for conserved positions and cylinders for helices are as in Fig. 1. Dashes indicate gaps. The typical homeodomain of Antp is shown at the bottom for comparison.

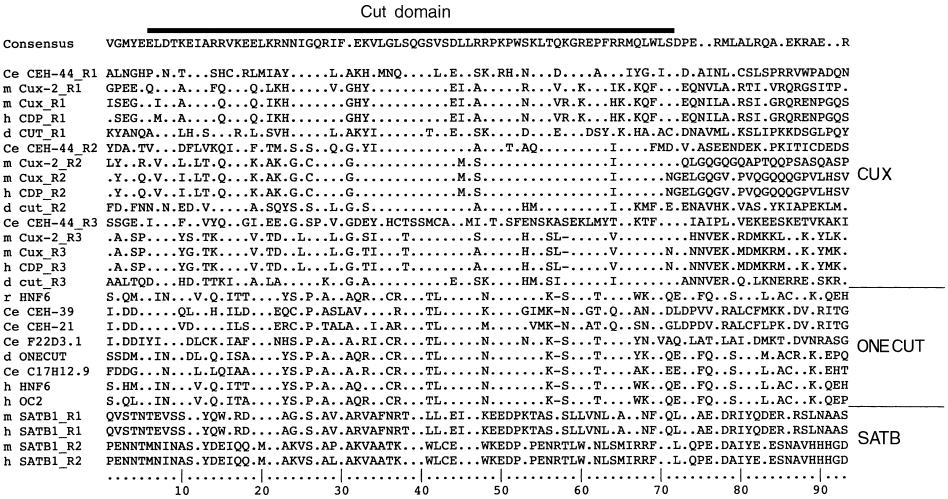

Fig. 15 Alignment of cut domain sequences. The genes of the CUX class encode three cut domains, marked by R1, R2, and R3, the genes of the ONECUT class encode only a single cut domain, and the SATB class genes encode two highly divergent cut domains (R1, R2). The black bar indicates the cut domain.

homeodomain. The cut domain is a DNA-binding domain. Other genes with cut domains have been discovered; however, their structural organization is quite different from that of *cut* so that four distinct classes can be defined (Figs. 4, 5, 15). The homeodomain sequences of these classes are rather different from each other, possibly because the presence of additional DNA-binding domains relieves the evolutionary pressure to maintain the homeodomain.

5.1 CUX Class

This class is defined by the fly gene *cut*, *C. elegans ceh-44*, the human transcription factor CDP, and other vertebrate homologs, which have been named *Cux* genes. These genes encode three cut domains upstream of the homeodomain. Unlike other homeodomain proteins, they have a histidine residue at position 50 of the homeodomain. Biochemical analysis

of the human CDP has revealed that the cut domain is a DNA-binding domain, like the prd domain and the POU-specific domain. The CUX class genes have a most unusual structural organization because, apart from the cut domain, their amino terminus is actually shared with another gene, CASP, which is a Golgi membrane protein. The amino-terminal half of CASP can either splice to the cut-homeodomain part of the Cux genes or it can splice to the carboxy-terminal part of the CASP protein, giving rise to a fully functional CASP protein. Sometime in evolution, an ancestral Cux gene has been functionally intertwined with the *CASP* gene through alternative splicing. This organization is found in *C. elegans* and vertebrates, but in *Drosophila*, the *CASP* gene has been lost.

5.2 ONECUT Class

The class is defined by a single cut domain. Most likely, this represents the most ancestral condition. Genes in this class comprise a diverse set of genes from *C. elegans*, for example, *ceh-21* and *ceh-39*, vertebrate HNF6 and OC2, and a single gene in *Drosophila*. In this gene class, position 48 of the homeodomain exchanges the tryptophan into a phenylalanine, or into a tyrosine in one divergent gene in *C. elegans*. Further, at the DNA-binding position 50, a methionine is found.

5.3 SATB Class

The genes of the SATB class encode two highly divergent cut domains and a highly divergent homeodomain. In addition, they have a new domain, called *COMPASS*, at their amino terminus (Fig. 4). Like the ONECUT genes, they encode a phenylalanine residue at position 48 of the homeodomain. SATB class genes have presently been found only in vertebrates. In contrast to other homeobox genes that act as regular transcription factors, SATB1 has been shown to be a special global gene regulator that is involved in chromatin remodeling.

5.4 COMPASS (CMP) Class

The CMP class of homeobox genes is an unusual group of homeobox genes that encode a CMP domain upstream of two homeodomains. The two homeodomains arose through duplication from a common ancestor. These homeodomains are distinct from those of other classes because of the extra residues in the loop region between helix 2 and helix 3 (Fig. 14). Members of the CMP class have been found in *C. elegans* and in *Drosophila* (the gene *dve*), but not in vertebrates. Even though the *CMP* genes do not encode cut domains and their homeodomains are highly different from other cut homeodomains, they are classified into the cut superclass because they share the CMP domain with the SATB class of genes. Since the SATB class is only found in vertebrates and the CMP class only in insects and nematodes so far, it may be possible that these two classes are orthologous.

6 ZF and LIM Classes

These two classes share the common trait that their genes encode zinc-binding domains in addition to the homeodomain. Each class encodes distinct types of zinc-binding domains: the ZF class encodes zinc fingers of the C_2-H_2 (two cysteine

residues–two histidine residues) type, and the LIM class, two copies of the LIM domain zinc finger. Some of the homeodomains of the ZF class proteins are more similar to LIM class homeodomains than to any other homeodomain. Thus, these two homeodomain classes may have arisen from a common single ancestor, but this is presently unresolved.

6.1 ZF Class

This is without question the most bizarre class of homeobox genes. While one *Drosophila* gene *zfh-1* encodes 9 zinc-finger domains and one homeodomain, another gene *zfh-2* has 16 zinc fingers and 3 homeodomains. The human homolog of *zfh-2, ATBF1* encodes 17 zinc fingers and 4 homeodomains. The zinc-finger domains are of the C_2-H_2 type, the same type that is also found in the developmental control genes *Krüppel* and *hunchback* in *Drosophila*. At least two families exist, defined by Drosophila *zfh-1* and *zfh-2*, that are conserved in vertebrates. The homeodomains of these proteins are very divergent (Fig. 5); presumably, the evolutionary constraints are relaxed because of the large number of DNA-binding domains present in a single protein.

6.2 LIM Class

LIM homeobox genes encode two LIM domains upstream of the homeodomain. The LIM domain is about 60 amino acids long and contains conserved cysteine and histidine residues (Fig. 16). It was first defined in two *C. elegans* genes, *lin-11* and *mec-3*, and in the rat transcription factor *Isl-1* (*lin-11, Isl-1, mec* − 3 = LIM). The LIM domain exhibits relatively poor primary sequence conservation between different proteins, and the first and the second copy are somewhat distinct from each other. The key residues are the conserved cysteine and histidine residues. The LIM domain has been shown to be a zinc-binding domain, a so-called *zinc finger*. The cysteine residues (positions A, B, and D) and the histidine residue (position C, Fig. 16) coordinate one zinc, while the second zinc is coordinated by three cysteine residues (position E, F, and G) and one residue that can be either a cysteine, histidine, or aspartate (position H). This double zinc finger is distinct from other zinc fingers, such as for example, the ones of the ZF class. The LIM class homeodomain sequences are much better conserved than the LIM domains and can thus be used for classification. Six families have been described: apterous (ap), LHX6/7, ISLET, LMX, LIM3, and LIN-11/LIM1.

The LIM domain is also present in genes that do not encode a homeodomain. The rhombotin genes (*LMO*, i.e. LIM-only) encode two LIM domains that are similar to the two LIM domains of LIM homeobox genes. Possibly, this gene family may have lost the homeodomain. A large number of other proteins containing only LIM domains have been found that are more divergent. The following are a few examples: mammalian CRIP, a cysteine-rich intestinal protein; ESP1, an estradiol-stimulated protein in brain; hCRP, a human cysteine-rich protein; zyxin, a cytoskeletal protein; and MLP, a regulator of myogenesis. hCRP and MLP, which are very similar to each other, have two copies of LIM that are more closely related to each other than to other LIM domains. CRIP and ESP1 have only one copy, and zyxin contains three LIM domains.

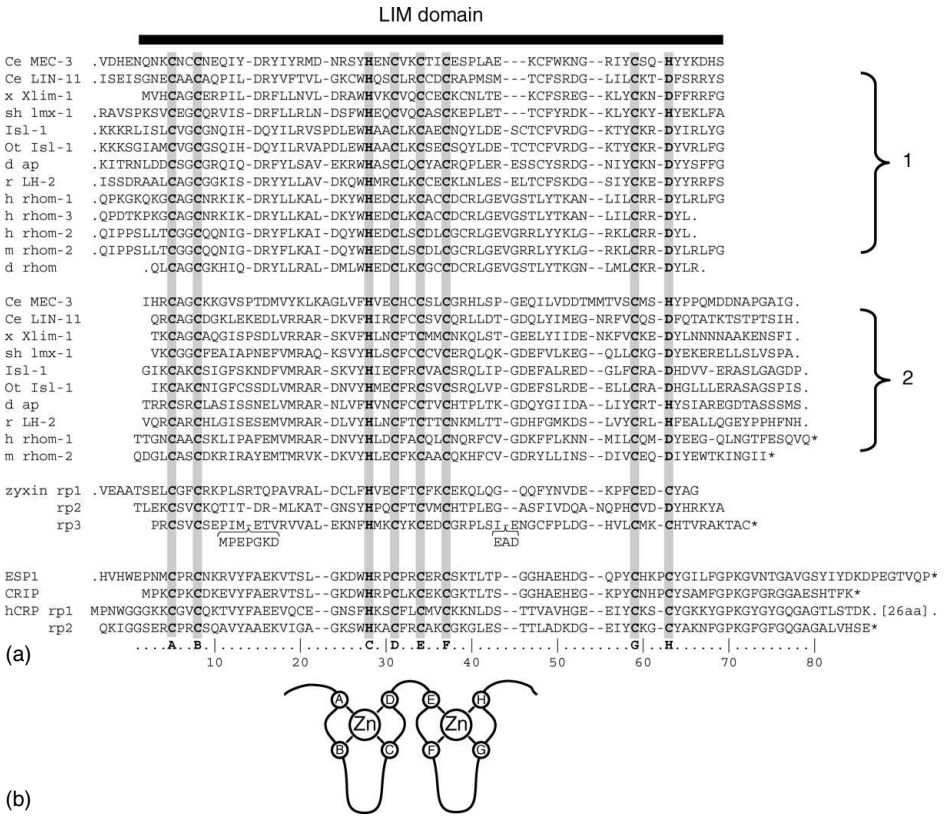

Fig. 16 Alignment of LIM domain sequences. LIM homeobox genes encode two LIM domains, the two parentheses on the right indicate the first and the second LIM domain, respectively. Several proteins, whose LIM domains are somewhat distinct and that have no homeodomain (i.e. zyxin, ESP1, CRIP, hCRP), are listed at the bottom. The conserved cysteine and histidine residues, which are the key residues for zinc binding are highlighted. At the bottom is a schematic view of the structure of the two zinc fingers; residues A to H are also indicated underneath the alignment.

The LIM domain is protein–protein interaction domain. For example, biochemical characterization of zyxin indicates that it is a zinc-binding protein that binds to α-actinin and is associated with the actin cytoskeleton. In addition, zyxin directly interacts with the chicken homolog of hCRP *in vitro*. The LIM domains of LIM homeobox genes also function in protein–protein interactions. One important interacting partner in that case is the LIM-binding protein Ldb. Thus, while the LIM domain can occur in multiple functional roles, the common denominator of these functions is protein–protein interaction.

7 Six/so Class

This class was originally defined by the *Drosophila* gene *so* and the mouse

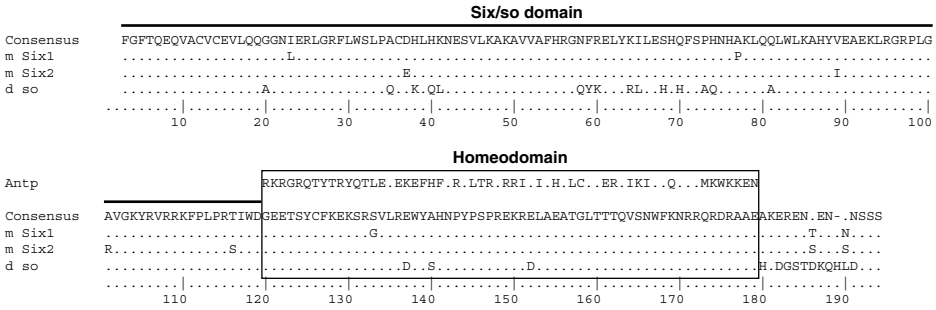

Fig. 17 Sequence alignment of Six/so class genes over the region of the Six/so domain and the homeodomain. The Six/so domain is marked by a black bar. The Six/so homeodomains are compared to the Antp homeodomain.

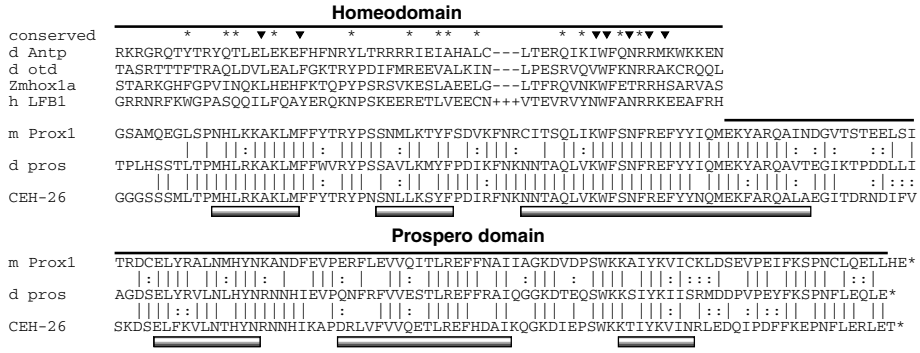

Fig. 18 Alignment of prospero class sequences. The lines between sequences indicate identities and colons mark similar amino acids. The "‡" marks matches of the pros class homeodomains to the highly conserved residues of typical homeodomains, which are shown at the top. The homeodomain as well as the pros domain are marked by black bars. The cylinders underneath the sequence show the α-helices derived from the structure of the Homeo-Pros domain.

genes *Six1* and *Six2*. These homeobox genes encode highly divergent typical homeodomains (Figs. 5, 17) that have a lysine at position 50 of the homeodomain. In addition, there is a highly conserved domain upstream of the homeodomain (Figs. 4, 17), the Six/so domain, which is about 120 amino acids long. The Six/so class of genes can be subdivided into three families, Six1/2, Six3/6, and Six4/5, which are all conserved between flies, worms, and vertebrates.

8
Prospero (Pros) Class

This class of atypical homeobox genes has been defined on the basis of the *Drosophila* gene *prospero*, the mouse gene *Prox 1*, and a *C. elegans ceh-26* (Fig. 18). It is a small class with a single member in fly and *C. elegans*. The pros class homeodomain is highly divergent and has three extra amino acids between helix 2 and helix 3. The highly conserved leucine in helix 1 is replaced with an alanine (Figs. 1,

18). Downstream of the homeodomain is a conserved sequence motif of about 100 amino acids, the pros domain, that reaches to the carboxy-terminus. The structure of the pros homeodomain and pros domain has been determined and confirmed to be a homeodomain. The pros domain forms a single structural unit with the homeodomain and is required for sequence-specific DNA binding.

9
TALE Superclass

As mentioned above, the TALE homeobox genes are characterized by having three extra residues in the loop between helix 1 and helix 2 of the homeodomain (three amino acid loop extension, Fig. 6). This group is ancient since members are found in plants, fungi, and animals. Four classes are found in animals, two in plants, and two distinct types in fungi. Many of the TALE superclass homeobox genes encode an isoleucine at position 50 of the homeobox.

9.1
PBC Class

Extensive sequence conservation outside the homeodomain has been found between the three human homeodomain proteins PBX1 (a protooncogene), PBX2, PBX3, the *C. elegans* homeodomain protein CEH-20, and the *Drosophila* protein extradenticle (exd). This new motif has been termed the *PBC domain* (Fig. 19). The PBC domain is bipartite (PBC-A and PBC-B), with a linker region between the two subregions, and about 180 amino acids long. The extended loops between helix 1 and helix 2 of the homeodomain of PBC proteins interacts with the Hexapeptide of Antp superclass homeobox genes, such as those of the lab family. Thus, PBC class genes form complexes with at least some of the HOX cluster genes. The homeodomain of PBC class genes contains a glycine residue at position 50 of the homeodomain, which is unusual as this residue can contact the DNA only via water-mediated interaction.

9.2
MEIS Class

The MEIS class of homeobox genes was first defined by the vertebrate *Meis* genes, *C. elegans unc-62 (ceh-25)*, and *Drosophila homothorax* (*hth*). As in the PBC class, a conserved, bipartite domain is found upstream of the homeodomain, called *MEIS* or *HM* (Fig. 20), which is about 130 amino acids long. Two subgroups can be

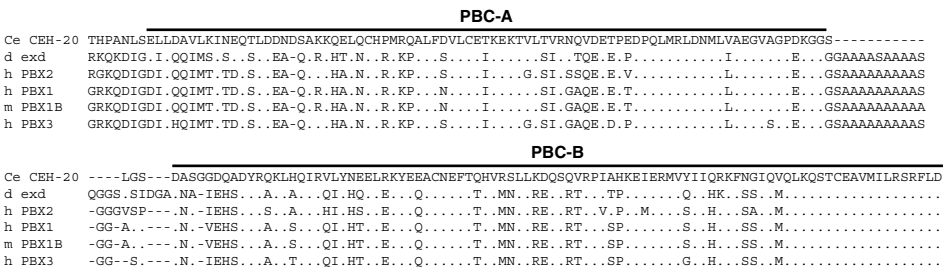

Fig. 19 Alignment of PBC domain sequences. The black bar indicates the conserved regions of the bipartite PBC domain, denoted by PBC-A and PBC-B.

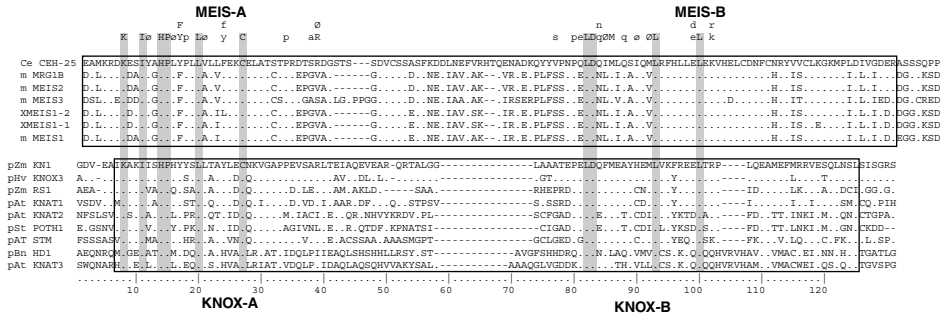

Fig. 20 Alignment of MEIS and KNOX domain sequences. The upper half shows the boxed MEIS domain, which is bipartite, consisting of MEIS-A and MEIS-B. The lower half shows the boxed KNOX domain, which is also bipartite, consisting of KNOX-A and KNOX-B. The gap in the linker region between KNOX-A and -B was increased to obtain alignment with the MEIS domain. Those residues that are absolutely conserved between MEIS and KNOX are shaded, other less-conserved positions are indicated on top of the MEIS domain; Ø represents hydrophobic residues.

defined, one based on the vertebrate *Meis* genes, and one based on the *Prep* genes. The MEIS-A region of the Prep proteins is shorter compared to Meis proteins (not shown). Fly hth and vertebrate Meis proteins interact with PBC class homeo domain proteins through their MEIS domain, which interacts with the PBC-A region. Thus, MEIS and PBC class proteins can form heterodimers. It has been shown that the interaction of hth with exd is responsible for translocating exd from the cytoplasm to the nucleus so that dimerization controls the activity of the protein complex. Further, MEIS class proteins can also interact with HOX cluster proteins that are expressed posteriorly (e.g. HoxA-10). Triple complexes of PBC, MEIS, and Hox proteins have also been reported. These combinatorial possibilities provide ample opportunities to generate many different types of DNA-binding specificity, and it is likely that the interaction between TALE homeobox genes and HOX cluster genes has been an important factor in the evolution of animal pattern formation.

9.3 IRO Class

The IRO class of TALE homeobox genes are defined by the *Drosophila* genes *araucan, mirror,* and *caupolican*. These genes are arranged in tandem in a gene cluster, the iroquois complex. Also, in mammals, there are two paralogous Irx gene clusters with three genes each. However, it is likely that the clusters evolved independently in flies and vertebrates and that only a single common ancestral *IRO* gene existed. The homeodomain of the IRO class genes contains an alanine residue at position 50 of the homeodomain (Fig. 6) and thus may have a DNA-binding activity distinct from other TALE homeobox genes. The IRO class of TALE homeobox genes share a small motif of about 12 amino acids, the IRO box, downstream of the homeodomain (not shown).

9.4 TGIF Class

The TGIF class of TALE homeodomains has been first defined by the vertebrate

TG-interacting factor (TGIF), but an orthologue has also been identified in *Drosophila*. Fly and vertebrate *TGIF* genes share an additional 20 amino acids immediately downstream of the homeodomain (not shown), *C. elegans* appears to have lost the *TGIF* gene. *TGIF* genes may have been derived from a MEIS class gene during the evolution of early animals.

10
Evolution of Homeobox Genes

10.1
Fungal Homeobox Genes

Seven homeobox genes are known in the yeast *Saccharomyces cerevisiae*. Two of these genes, *MATa1* and *MATα2* are part of the mating type locus (MAT); *MATa1* encodes a typical homeodomain and *MATα2* a TALE homeodomain. Such a dyad of a typical and TALE homeobox gene is also found in other fungi, such as *Ustilago maydis*, *Schizophyllum commune*, and *Coprinus cinereus*. That these genes are indeed evolutionarily related is further supported by the fact that the typical homeobox genes *MATa1*, Um *bW*, and Sc *AαY* have an intron in the same position in the homeobox. Also, in Microsporidia, a closely linked pair of homeobox genes has been found, one a typical and one a TALE homeobox gene. While the function of this locus is not yet known, it does show that a locus with a typical and a TALE homeobox gene is an ancestral feature in the fungal lineage. In yeast, MATa1 and MATα2 form heterodimers, and MATα2 also forms homodimers, allowing regulation of different sets of target genes. Classification of the fungal homeobox genes, apart from the distinction of typical and TALE homeobox genes, is not readily possible due to their divergence, and no additional conserved domains are encoded by these homeobox genes that would aid in classification. Phylogenetic analyses of yeast and Microsporidia homeodomain sequences suggests that within each fungal branch, duplications of homeobox genes have occurred independently. In summary, it can be estimated that there were not more than two TALE homeobox genes and two to three typical homeobox genes present in the first fungal ancestors.

10.2
Plant Homeobox Genes

In plants, 14 distinct classes of homeobox genes that have been conserved between monocots and dicots can be identified. One large group consists of homeobox genes that have a leucine-zipper, a protein interaction motif, downstream of the homeodomain. These genes can be grouped into four classes, HD-ZIP I, II, III, and IV. Samples of homeodomain sequences for two classes are shown in Fig. 5. Genes of HD-ZIP III and IV encode a START domain, a lipid-binding domain, downstream of the homeodomain. The START domain is also found in animals; however, there it is not found in homeobox genes. The homeodomain of the HD-ZIP III genes has undergone a drastic change, since in that class extra residues have been inserted between helix 2 and helix 3 of the homeodomain (not shown). Genes of the other classes also encode conserved domains outside the homeodomain. For example, the PHD class genes encode a PHD domain upstream of the homeodomain. The PHD domain is a zinc-finger motif distinct from the LIM and ZF class

zinc fingers. The DDT class genes encode a DDT domain downstream of the homeodomain. Both PHD and DDT domain are also found in animals – in fact, these two domains can occur in the same protein – but not in homeodomain proteins. Plants have two ancient classes of TALE homeobox genes, the KNOX class and the BEL class. Both encode large bipartite domains upstream of the homeodomain, termed *KNOX* and *BEL domain*, respectively. The KNOX domain (Fig. 20) can be aligned with the MEIS domain, showing that these two gene classes in plants and animals have arisen from a common ancestral TALE homeobox gene that also encoded, what we termed, the *MEINOX domain*. The BEL domain (not shown) has some weak similarities to the MEIS domain and may be derived from it. BEL and MEIS proteins have been shown to interact and this interaction is mediated through their BEL and MEIS domains, respectively.

10.3 Origin and Diversification of Homeobox Genes

The different classes of homeobox genes found in plants and animals have arisen mainly independently of each other. The only group of genes that can be clearly traced from a common ancestor are the TALE homeobox genes, in particular, the MEIS and KNOX class of homeobox genes. The PBC domain in animals has also been shown to have similarity to the MEINOX domain, and the BEL domain in plants may have similarities as well. This suggests that there was at least one MEINOX-TALE homeobox gene in the common ancestor organism (CAO) that gave rise to plants and animals. Both plants and fungi each have two rather distinct classes of TALE homeobox genes, that is, KNOX and BEL in plants and CUP and M-ATYP in yeast (Fig. 6), and animals have four, although the two main ones are PBC and MEIS. Thus, the possibility remains open that there were two TALE homeobox genes in the CAO. For typical homeobox genes, the situation is less clear. Again, there probably must have been at least one in the CAO. Since, in fungi, perhaps not more than three different types of typical homeobox genes exist, there should not have been more than three in the CAO either. Thus, the CAO must have had at least two, but not more than five homeobox genes. A single "Urhomeobox" gene must have given rise to the typical and TALE homeobox genes, but at present, we do not know whence it came from. The homeodomain is structurally related to bacterial helix-turn-helix proteins, so in some protozoa, a helix-turn-helix protein seems to have become the first homeodomain protein.

It is interesting to note that TALE homeodomain proteins form homo- or heterodimers in plants, fungi, and animals. Further, both in fungi and animals, typical homeodomain proteins, in animals, those from the HOX cluster, and TALE homeodomain proteins also interact. It suggests that these interactions are of an ancient nature and probably were already present in the CAO. In animals, the diversification of the homeobox genes has led to a large proliferation of different classes and families. The last common ancestor of all higher animals, that is, protostomes and deuterostomes, already contained the diversity of all the different homeobox classes. Counting the different conserved gene families, at least 70 different homeobox genes must have already been present in that animal.

Present day organisms such as *Drosophila* and *C. elegans* have around 100 homeobox genes, while vertebrates, because of the large-scale duplications in early vertebrate evolution, have more than 200. While there are many other types of transcription factors encoded in an animal genome, the homeobox genes are perhaps the most important group that played essential roles in shaping the evolution of animals.

Keywords

Bacteriophage (phage)
Viruses specific to bacteria.

Competition Model
Derives from an experimental demonstration of the evolutionary forces that determine when genes reproduce by HGT. On the basis of the hypothesis that different genes reproduce faster by HGT in different environments and the change in environment determines when genes become mobile. Stability of the environment then influences which genes introgress. Produces unique predictions of how genes are recruited to HGT vectors.

Complexity Hypothesis
Posits that genes least likely to introgress are of a type that are involved in highly interdependent large biochemical complexes. The interactions lead to constraints that would preclude replacement by genes that have diverged.

Conjugation
A form of DNA transfer mediated by infectious elements (called *plasmids*) normally found in bacteria. Plasmids transfer from bacteria to all known forms of life.

Hybridization (to form hybrids)
The initial product of a sexual cross between individuals that are considered to be of different varieties, subspecies, species, or genera and that might often be revealed by low fecundity or infertile offspring.

Introgression
''The permanent incorporation of genes from one set of differentiated populations (species, subspecies, races, and so on) into another'' (quote from Stewart Jr. et al.).

Phylogeny
The evolutionary connections between organisms inferred from assumed descent via a common ancestor.

Transduction
The transfer of genes by viruses to different organisms within the infectious range of the virus.

Transformation
The change in the phenotype of organisms due to the inheritance of a gene. In molecular biology jargon, it often is a term that also refers to the uptake of DNA regardless of whether it alters the phenotype.

Vectors
Viruses, gametes, organisms, plasmids, or other agents that can deliver genes by HGT.

Vertical Gene Transfer
Reproduction of genes in the context of whole genome replication and reproduction of the organism or entire cell of an organism.

Horizontal gene transfer (HGT) may be defined as any occurrence of heritable material passing between organisms, asynchronous with reproduction of the organisms. It represents replication of heritable material outside the context of parent to offspring (i.e. vertical) reproduction. Three types of evidence traditionally lead to claims of HGT. Firstly, biochemical and genetic observations of real-time (usually laboratory recreations of) gene flow between two genotypically distinguishable individuals. Secondly, DNA sequences that are common within a species but inconsistently found in that genus, and finally, direct evidence of processes that can create genes that reproduce horizontally. HGT is now confirmed to occur between all biological kingdoms and has consequences even when genes fail to introgress.

1 Horizontal Gene Transfer Versus Introgression

Awareness of HGT (horizontal gene transfer) has risen in recent times in part due to some spectacular scientific debates surrounding, particularly, the release of genetically modified organisms (GMOs) as food crops and the spread of antibiotic-resistant bacteria that cause disease. The recent controversies belie the long history of research in HGT, sometimes treating it as if it had been discovered only since genome sequences began to be completed. On the contrary, HGT is a general and pervasive biological phenomenon, but it has been packaged into separate boxes that go by other names. We attempt here to identify what is fundamental to HGT so that it may be recognized in the various other boxes it appears in, and to place it center stage in the modern scientific discourses that depend on understanding it.

There is genuine confusion about what HGT is and what it is not. Part of this confusion results from semantics, with some authors simply preferring the term lateral gene transfer (LGT) to HGT. To resolve this issue, C.I. Kado suggested that the term LGT be reserved for gene transfers between closely related partners and HGT for more distant. This proposal has some merit, but it presupposes that the important defining characteristic of HGT resides in the organisms that are donors and recipients of genes rather than the genes themselves. Besides the obvious problem of knowing when partners are close enough to call exchanges between them (LGT), it is entirely possible for two partners to swap a gene that is

phylogenetically more distant to both the donor and recipient than either is to one another.

The most important source of confusion is the tendency to substitute an outcome of HGT with a description of HGT. Two outcomes are most commonly associated with HGT. One outcome is that HGT can generate genotypic diversity in a species or offer a selective advantage to recombinants within a species. This has tempted many to consider HGT a process by which organisms, especially the asexual bacteria, recover some of the benefits of sex. There is no denying that HGT can provide genes that benefit the recipient and introduce genetic diversity into populations, but these outcomes are based on the biology of the recipient organism and are only one of the consequences of HGT.

A second outcome is introgression. Genes, and sometimes entire chromosomes, can be introduced into a separate, differentiated population. For a gene to become permanent, it almost certainly must have provided an adaptive function, or survived a fortunate bottleneck. Moreover, the recombinant genome must be found in many if not all individuals of a species. For that to occur, the recombinant genome must outcompete most or all genomes that lacked the new gene.

The concept of introgression is normally reserved for describing vertical gene transfer over the barriers erected by meiosis. However, aspects of the concept also apply to HGT. Whether an alien gene is introduced during (e.g. hybridization) or asynchronously with reproduction (i.e. HGT), there are barriers to it becoming a stable and common part of the genome of the species. Alien genes likewise must be present in a significant proportion of a population in order to be detected. Overcoming these barriers can lead to alien genes and chromosomes becoming a characteristic feature of a species.

The process by which genes introgress, however, is only part of the way genes evolve by HGT (Fig. 1). Genome sequencing reveals past gene transfers by finding alien genes in genomes. The number of alien genes found by such methods only reflects the number of genes that have introgressed, not the number or frequency of transfer. This one outcome of HGT is certainly important evidence for HGT, but it is ill suited to measuring its impact and frequency. Measurements of HGT that rest with genomic DNA sequences are essentially a measure of the range and frequencies in which genomes retain genes, not the range and frequencies of gene transfers that make the genes available in the first place (Fig. 1).

Making HGT the same as an outcome of HGT, namely, the ''acquisition of 'alien genes' by a particular genome'' (quote from Koonin et al. in Syvanen and Kado) substitutes historic description for understanding how HGT happens biochemically and how it influences organisms physiologically. Quite rightly, this focus leads to strong criticisms about proper identification of DNA sequences that are indeed alien.

Understanding how genes introgress, therefore, is not the same as understanding HGT. HGT is not limited to transfers that change organismal genotypes. For example, some genomes may evolve almost exclusively by HGT. Viruses and transposable elements like *mariner* are arguably the product of evolution that has little to do with organismal genomes and their vertical reproduction.

The essence of HGT as an evolutionary process, and not just an outcome, must be preserved in any definition. HGT may

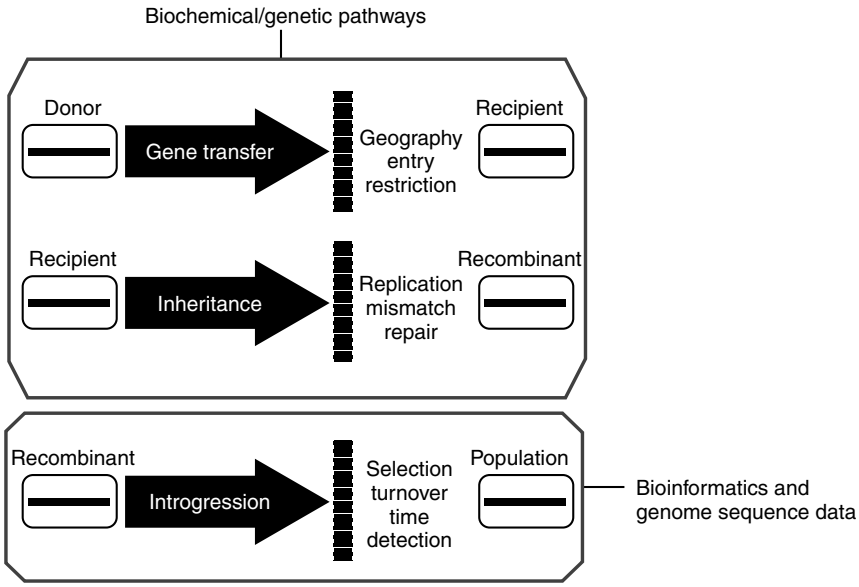

Fig. 1 Different levels of analysis used to study horizontal gene transfer. Symbols: rounded rectangles = cells or organisms, solid rectangles = mobile gene, brick wall = listed barriers. Only process experiments as discussed in Sect. 3 can cover all levels.

be defined as any occurrence of heritable material passing between organisms, asynchronous with reproduction of the organisms. It represents replication of heritable material outside the context of parent to offspring (i.e. vertical) reproduction. This definition permits different means of transfer – such as viruses or transduction, conjugation, and transformation – and different outcomes of transfer – such as serial infection or recombination – to be united in legitimate study about how genes evolve through HGT.

2 Vectors and Pathways of HGT

2.1 Transformation and Pathogenic Bacteria

Bacteria can at times become competent for the uptake of DNA from their surrounding environment. Should part or all of that DNA become stably incorporated into the genome, they are called *transformants*. Competence may be expressed constitutively in a proportion of the population or be induced. It is usually associated with the expression of a set of proteins, called *com* for competence, that include or are in addition to structures (e.g. vesicles and pili in some gram-negative bacteria) associated with the ability to bind extracellular DNA and translocate it into the cytoplasm.

The most widely studied examples of naturally competent bacteria are *Streptococcus pneumoniae* and *Bacillus subtilis* (of the gram-positives) and *Haemophilus influenzae* and *Neisseria gonorrhoeae* (of the gram-negatives). Although the molecular details of transformation varies between organisms, in each case DNA is taken into the cell in single-stranded form where it is thought to serve as a substrate for

single-strand specific DNA binding recombinases (e.g. analogs of *Escherichia coli's* RecA protein) that initiate a search for similar sequences of DNA in the recipient genome. This recombination process is aborted or reversed, depending on the activities of the endogenous mismatch-repair (MMR) pathways, if the incoming strand creates too many mismatched base pairs. Depending on the efficiency of MMR at the time, the incoming DNA may survive through a subsequent round of DNA replication and become immortalized in the recipient genome.

The uptake process has been characterized to the molecular level for a small number of bacteria and a small number of environmental conditions that induce competence. Many bacteria that are not known to be competent have homologs of *com* genes, which might indicate that they do have the potential to take up DNA from the extracellular environment. It remains unknown how many bacteria may take up DNA and all the environments in which they may be induced to take up DNA naturally. Even the icon of noncompetent bacteria, *E. coli*, was recently shown to develop a natural competence in laboratory studies.

In contrast, no special competence seems to be required for eukaryotic cells to take up DNA by transformation. DNA can pass into animal cells *in situ* simply through food and has been reported to pass through the placenta and recombine into the mammalian genome. Animal cells can also be transformed *in vivo* and *in vitro* using bacteria that cross into the cytoplasm. Viruses also can produce proteins that serve to transfer genes within multicellular organisms, bypassing the need to reinfect from the outside.

2.2 Conjugation

Bacterial conjugation in its broadest sense includes the conjugative plasmid groups discovered in gram-negative bacteria, the T-DNA of the Ti plasmid, pheromone-responsive plasmids and conjugative transposons. The focus in this overview is on the model conjugative systems defined by the IncP and IncF groups of plasmids of gram-negative bacteria.

Plasmids are similar to viruses but they lack any known extracellular form. Though loosely defined as extrachromosomal, like some viruses they can be found integrated into chromosomes at times. They have also been defined as accessory elements or parasites because hosts cured of plasmids can survive and reproduce in at least one environment. Conjugative plasmids got their name because for a time it was thought that they replaced the need for sex in prokaryotes. This idea derived from the use of genes with adaptive value, such as antibiotic resistance genes, to monitor the transfer of the plasmids. None of the above-mentioned characteristics is universal, so we have opted to define plasmids by their ability to reproduce in at least one environment in which the host cannot. That niche may not be physical but temporal, such as provided by HGT.

Conjugation mediated by the IncF and IncP plasmids requires, at a minimum, a cis-acting DNA sequence called *the origin of transfer* (*oriT*). All other functions (called *tra*) act in trans thus allowing plasmids with all trans-acting functions to also transfer plasmids with no or a few trans-acting functions. The trans-acting gene products are divided further into those involved in DNA metabolism (and usually specific to a particular *oriT*) and those involved in DNA transport

and cell–cell interactions (and thus most likely to interact with a greater range of other plasmids). The conjugative genes that are specific to DNA metabolism introduce a ''nick'' at *oriT* and initiate the unwinding and concomitant transfer of DNA to a recipient cell. Both strands are used as templates for the synthesis of a complementary strand, one in the donor cell and one in the recipient.

The tumor-inducing (Ti) plasmid from *Agrobacterium tumefaciens* is a plasmid with two conjugative systems. One system mobilizes the entire plasmid; the second system mobilizes a single region of the plasmid, called *the T-DNA*. It is the T-DNA that is recovered from crown gall tissue of plants infected by *A. tumefaciens*, a discovery that unambiguously demonstrated that conjugation was a means to transfer DNA across biological kingdoms.

It has become clear over the past decade that the DNA transport apparatus of conjugation is the ancestor, or at least a sibling, of other macromolecular transport systems such as the type IV protein secretion pathways. Bacteria that secrete proteins into human cells during infection may also secrete plasmids using the same apparatus. Consistent with this speculation is the ability of conjugative plasmids to transfer from bacteria to eukaryotic cells, and the ability of bacteria to support conjugation *in situ* and inside human cells.

2.3 Parasites, Symbionts and Pathogens

Parasites, symbionts, and pathogens are excellent gene vectors. Viruses, like many pathogens, can have much broader transfer ranges than symptom ranges. Some viruses transfer between plants and animals, and bacteriophage can penetrate the human central nervous system. These vectors also transmit a wide range of molecules in addition to DNA, such as RNA and proteins. These molecules are relevant here because prions and dsRNA are horizontally transferred epigenes capable of transforming the germline.

2.3.1 Viruses and Transduction

Transduction is formally viral-mediated transfer of nonvirus genes between hosts. While it is not uncommon for viruses to acquire genes from their hosts, and thus acquire new virulence or host range characteristics, transduction is distinctive because, like transformation, it delivers genes most recently of chromosomal origin that become stably integrated into the recipient genome.

Generalized transducing bacteriophage, the viruses specific to bacteria, package host DNA instead of viral DNA at some low frequency during infection (on the order of 0.001%). This phenomenon is called *generalized transduction* because any region of the chromosome may be packaged. The size of the phage determines how much DNA may be transduced by a single phage, which is normally only 1 to 2% of the host genome. The mature phage particle retains the ability to attach and initiate an infection, but delivers cellular rather than viral DNA to the recipient. Since the phage particle does not contain the viral genome, the infection does not result in the production of new viruses.

All temperate phages that integrate into a chromosome as a part of their life cycle have the potential to be *specialized* transducing phage. During the process of excising from the chromosome to begin an infectious cycle, DNA flanking the phage genome can be packaged at some low frequency. This phenomenon is known as *specialized* because only a small number of

genes are ever transduced by this phage. Phage integrating into the chromosome usually does not enter at random, but instead enters at special DNA sequences in the host chromosome. Thus, it is only the genes flanking integration sites that are transduced.

Bacterial genomes are littered with the skeletons of phage, many of which no longer have an infectious life cycle. These skeletons are revealed when they are the source of genes that promote bacterial virulence (pathogenicity islands) or symbiosis (symbiosis islands). They may also provide sequences into which still active temperate phages could integrate by homologous recombination or by a site-specific mechanism. These phage remnants also make it difficult to say what a host gene is and what a viral gene is not. This ambiguity is part of the reason why we consider viral infection itself a demonstration of HGT rather than simply when an arbitrary marker is acquired in the course of a phage infection.

2.3.2 Parasitic Plants

Around 1% of all flowering plants (angiosperms) are parasitic, attaching to host plant species from which they extract some, if not all, of the carbon, nutrients, and water they require for growth. Some of these parasites, like the Rafflesiaceae, have evolved to such an extent that the only outward signs of the parasite are when they exit the host to flower. It has long been known that parasitic plants not only exchange carbon and nutrients with their host but that they also exchange complex molecules like alkaloids and pathogens including viruses, bacteria, and phytoplasmas. This intimate relationship may also facilitate HGT between plant species. A multigene phylogenetic analysis of the parasitic Rafflesiaceae has shown that some genes from both the nuclear and the mitochondrial genomes are distinct to the order Malpighiales while other mitochondrial genes are closely associated with their obligate host *Tetrastigma*. The Rafflesiaceae are obligate host parasites, meaning that they only parasitize one host species. However, other parasitic plant species like the *Cuscuta* can attach to a broad range of hosts and can even simultaneously parasitize multiple hosts. This raises the possibility that any one host species may be continually exposed to DNA (either naked or within vectors like viruses and bacteria) from multiple, unrelated species. It will not be surprising if introgressions of many genes are discovered because of the long and continuing history of plant–plant parasitism.

2.3.3 Parasitic and Pathogenic Animals

The massive transfer of DNA to eukaryotes is widely believed to have happened when the different kinds of symbionts or parasites, such as those that were the free-living relatives of the mitochondria and chloroplast, fused with the common ancestor of eukaryotes. The transfer of DNA from organelles to the nucleus may have been a passive event, such as happens when invasive bacteria die inside animal cells, or an active process as indicated in laboratory studies following transgene transfer from yeast mitochondria to the nucleus.

Other intracellular parasites may transfer DNA to the host nucleus. Human, rabbit, and bird cells acquire the DNA from the parasite *Trypanosoma cruzi*, a protozoan that can cross the human placenta and transform the germline of animals.

The DNA donor *T. cruzi* is an example of a parasite/pathogen delivered to its human host by a biting insect vector. Other biting insects may be direct vectors of genes. The egg predatory mite *Proctolaelaps regalis* is

the most likely vector of P transposable elements to the Drosophilids. The mite does not have the element in its genome, so it may have introduced it into the germline of Drosophila after feeding on a carrier.

2.4 Hybridization

While hybridization is the outcome of sexual reproduction, it can also double as a vector for HGT. Even infertile hybrids can serve to promote HGT. For example, some hybrid plants convert to apomixis, an asexual mode of reproduction, increasing the chances of introgression. Infertile asexual hybrids or hybrids with low fertility may also produce offspring in time. When hybridization reduces fertility by creating two or more unmatched chromosomes, in time these chromosomes can duplicate, and thus pair. Once all the chromosomes again are partnered in meiosis, the hybrid can return to sexual modes of reproduction. Meanwhile, alien genes and transposable elements carried by alien chromosomes, whether or not the entire chromosomes should ever introgress, can transfer into the original genome.

The impact that mixing of previously separated populations has on the likelihood of interspecies gene transfer and introgression, should not be underestimated. Although there is an immediate increase in the chance of hybridization from breaking geographical boundaries between, say, a native species and an introduced one, the chances of more widespread gene transfer appear to be markedly increased if the introduced alien also acts as a bridging species, that is, a species that can link, through hybridization, two or more species that previously were genetically, geographically, morphologically, or physiologically separated to an extent that prevented hybridization.

These ''hybrid-bridge'' species have the potential to effectively act as multipliers of introgression, as they not only permit gene transfer between themselves and a resident native but also between multiple native and/or introduced species that were previously separated so much that the hybridization event was unlikely (Fig. 2). Simple examples of ''hybrid-bridge'' species can be envisaged: for example, a species with a flowering time that is intermediate between two resident species could allow gene flow between species previously separated by flowering morphology; likewise, a species with a broad habitat tolerance could link species from habitats that were previously geographically separated. In the face of current discoveries of gene introgressions through hybridization, it seems only a matter of time before an example of long-distance HGT driven by hybrid-bridge species is recognized.

3 Different Ways to Observe HGT

The science of horizontal gene transfer is well represented by researchers using two different but compatible approaches. The newest approach is to use bioinformatic descriptions of putative alien genes or tracts of alien DNA sequence to infer how and how often HGT happens, and what the consequences are to the recombinant genomes. This approach has the strength of looking over many different species simultaneously because of the accumulation of complete genome sequences and the rapid nature of *in silico* analysis. The bioinformatics approach of

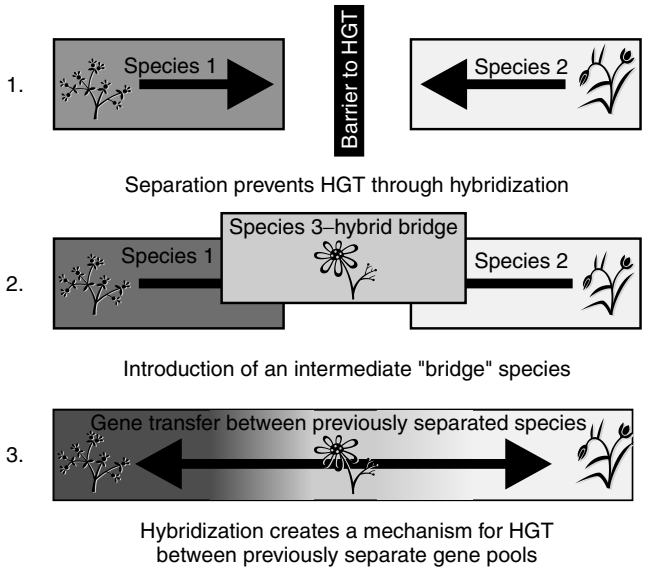

Fig. 2 Hybridization provides a mechanism for HGT between differentiated and separate multicellular eukaryotes. Symbols: rectangles represent populations of species in which HGT is confined; arrows represent the potential flow if genetic material in HGT. Removal of historical barriers to HGT, such as geographical separation, may lead to even greater potential for HGT. In this example, (1) two species may traditionally be unable to hybridize because of barriers such as habitat separation or differences in flowering morphology or physiology. (2) The introduction of a species that can hybridize with both Species 1 and 2 could bridge this separation. (3) The consequences of this ''hybrid bridge'' would mean that HGT, which previously could not occur between Species 1 and 2, would now be possible.

HGT, however, is limited by how well its techniques identify true HGT events, how accurate its predictions of gene function are, and by the very necessary fact that it is concentrating exclusively on DNA that has transferred, converted into vertically inherited material, and introgressed, that is, outcomes of HGT. Moreover, each event in the trillions of cells of a single large multicellular organism, or among the recipients of species that number 10^{20} individuals or more, is extremely easy to overlook. Below, the various bioinformatics tools for identifying HGT will be discussed.

The second approach is to observe HGT. Those observations can include biochemical descriptions of gene transfer pathways to eco-evolutionary experiments that measure how genes sort between horizontal and vertical mechanisms of inheritance. The experimental approach has the strength of using empirical biology to discover phenomena not immediately apparent from DNA sequences. It can in addition discover epigenes and other important molecules that may also transfer horizontally, and, importantly, it has the comparative power required to test

hypotheses about HGT processes. This approach is limited by the generation time of experimental organisms, the infrastructure needed to maintain different kinds of organisms, the realism of laboratory recreations of ecosystems in which gene transfers may occur, and the very limited capacity to physically sample enough biological material in order to detect HGT. Below, some novel process experiments and their relevance to understanding the ecology of mobile genes will be presented.

3.1 Descriptive Bioinformatics

Bioinformatics has produced compelling evidence from sequenced genomes of past gene transfers. Those transfer events that are detectable using bioinformatics are so because they are either

- recent;
- large fragments of DNA; or
- small but extremely different from the genome as a whole and out of place in the organismal phylogeny, in particular.

The introduction of new genes into a genome can create an anomalous phylogenetic tree, incongruent with other gene-based trees or trees built from morphological features. For example, the genes for the various aminoacyl tRNA synthetases, aaRS, create different phylogenetic trees in bacteria. This appears to result from different aaRS genes having been acquired by bacteria from various eukaryotes at different times. A particularly striking example is provided by ProRS, where a eukaryotic version is found in *Mycobacterium leprae* but not in the close relative *Mycobacterium tuberculosis*. In this case, the corresponding prokaryotic ProRS was lost from *M. leprae*; in some examples of aaRS transfer, both the prokaryotic and eukaryotic versions are maintained.

Evidence for HGT based on analyses that identify candidate genes that violate a phylogenetic order is prone to false-positive errors due, for example, to long-branch attraction. The most pervasive source of false-negative and false-positive identifications of alien genes comes from the initial construction of the tree based on putative orthologous genes. These genes diverged when the species diverged and represent the divergence of the two organisms from a common ancestor. However, they can be difficult to distinguish from paralogous genes created when a gene duplicates creating two alleles, which can then change independently over time. These reflect only the history of the genes within, instead of between, lineages.

Identifying which of multiple paralogous genes is a true orthologous gene is sometimes done by assuming that the most similar of the paralogous genes in the different species are the orthologous genes. However, accepting this *a priori* assumption can render the comparison redundant. Moreover, that test can never be independently verified because, no matter how close the sequences match, the possibility that one species lost the true orthologous gene since the speciation event can never be excluded. Indeed, the genes may be orthologous but because the gene was transferred horizontally, the comparison misrepresents the ancestry of the organism. Mistakes have been made by the inadvertent comparisons of paralogous genes.

Recent transfers may be indicated by a significant divergence in the composition of the DNA from the parameters expected on the basis of average characteristics of the genome. A horizontally transferred

gene preserved in a vertically reproducing lineage may be identified by a significant deviation from the average G + C content of the genome or from the normal codon bias of the host. Both of these indicators are quantitative. Thus, they are useful if large tracts of sequences with one or more large deviations from accepted norms are being analyzed.

The origin of sequences becomes increasingly difficult to determine the shorter they become or the closer to accepted ranges they appear. Shorter sequences may be the usual consequence of HGT that involves integration of alien genes with less sequence similarity to the recipient genome.

The outcome of many described HGT events is insertion of difficult-to-spot subgene domains. These nucleotide insertions, deletions, or replacements create ''mosaic'' genes that may have altered biochemical properties, for example, genes making bacteria resistant to antibiotics. Mosaics are caused by biochemical barriers, primarily MMR, that incompletely remove DNA during recombination.

MMR can saturate under stress or falter through mutation, promoting interspecies HGT ~10 000-fold and creating ''mutators.'' Depending on the proficiency and mechanism of MMR in an organism, strands of DNA from different species may initially be paired, with the invading strand subsequently degraded. Should some mispairs escape repair, or if the MMR machinery became saturated, stretches of the recipient genome could be ''massaged'' into a closer match with the donor DNA over short intervals.

Recombination frequencies can vary significantly depending on the activity of MMR, resulting in mosaic genes composed of sequences from two highly divergent genes. In fact, a mutation in bacteria is 50 times more likely to have occurred by recombination than by DNA damage or replication errors. Since mutations are often revealed by very small changes in DNA sequence, it is normally impossible to distinguish between their origin as a polymerase or a mismatch-repair error. Mosaic genes can serve as molecular versions of ''hybrid-bridges'' (Sect. 2.4), facilitating higher frequency recombination between species that find sequence similarity in some parts of the mosaic gene.

The added difficulty of identifying genes that transfer frequently is that they may not mutate at the same rate as genes that reproduce vertically. The genomes of horizontally mobile vectors tend to be fluid. Over time, certain vectors may be replaced by related vectors carrying different genes, such as plasmids with an expanding repertoire of antibiotic resistance genes. Tracing their ancestry by sequence structure allows relationships to be determined only over very short periods of time. For example, the structure of infectious retroviruses can change at 10^4 to 10^6 times the rate of other genes and defective retroviruses that are reproducing in synchrony with the host. The phylogeny of these viruses is confined to tracing the residues of defective viruses trapped in chromosomes of organisms or monitoring divergences only on decade timescales.

Determining ancestry of organisms without relying upon nucleic acid or protein sequences is possible, but much more difficult. In the cases of ribonuclease H and the A8 subunit of mitochondria, ancestry was inferred from three-dimensional structures or other biophysical characteristics because the primary nucleic or amino acid sequences had lost such information.

3.2 Experimentation

Within the experimentalist approach are two mutually supportive schools. The first school is characterized by a quest to understand the biochemistry and pathways behind observable gene transfers. The work of that group is well represented in the literature on conjugation, transduction, and transformation. The second school elevates HGT to an evolutionary process – like sex, mutagenesis, or symbiosis – that can be characterized by how it evolved and to what selective forces it responds to.

3.2.1 Seminal Experimentalist Approaches

The origin of the experimentalist approach for studying HGT can be traced to the first description of mechanisms, including the pioneering work of the 1940s and 1950s with phage, transformation, and conjugation. Those studies were overtly focused on the biology of the organism or the vector, rather than on how HGT shaped them. For example, Luria and Delbrück's famous experiment measuring phage resistance had little to do with understanding how viruses themselves evolved, but it required a comprehensive understanding of the life cycle of the phage in order to demonstrate an evolutionary truth about whether mutations follow or precede selection. Avery et al. used natural competence in *pneumoccocus* to all but prove that DNA was the source of the genes behind the virulence traits they studied, but they used HGT to identify the transforming principle rather than using the transforming principle in a study of HGT. Hayes' use of the antibiotic streptomycin revealed the unidirectional transfer of genes from a donor to recipient by conjugation, but it would take almost 40 years before his trick was resurrected to begin to understand why horizontally mobile plasmids would come to carry antibiotic resistance genes.

In the late 1960s, research groups with a specific focus on HGT emerged. Their pioneering work provided the first hints that both proteins and DNA and RNA could physically transfer between species. The team of Maurice Stroun and Philippe Anker were arguably the first to detect hints that gene transfer from the plant pathogen *A. tumefaciens* was behind the crown gall tumors it caused. This work would take another 10 years, and a suite of new techniques, to be confirmed. Stroun and Anker also produced compelling evidence with the techniques of their time for the horizontal transfer of proteins, a theme that has gained prominence with the demonstration of the interspecies infectivity of prions and the description of the Type IV DNA and protein secretion systems that bacteria use for both conjugation and the transfer of proteins to eukaryotic hosts. What made the work of Stroun and Anker different from that of their contemporaries was that while they were inspired by the biology of the organisms they chose, their experiments were process-oriented, designed to detect gene transfer rather than to focus on the biology of particular organisms.

3.2.2 Modern Process Approaches

Research that focuses on the process of HGT is becoming more prominent, especially as the threat of gene transfer from transgenic crops and antibiotic-resistant bacteria command the attention of the scientific community. Past descriptions of gene transfers and full descriptions of biochemical mechanisms, when available, have proved of limited use in predicting

when, where, and how often gene transfer might create an unwelcome biological outcome. In this section, two contemporary models that promise predictive power are contrasted.

Why and when are some genes reproducing horizontally while other genes, or at other times these same genes, are reproducing vertically? Two different models have been constructed in answer to this question. The first model, called *the complexity hypothesis*, argues that some genes are more mobile than others simply because of the complexity of the processes in which they are involved. Those genes whose products are closely reliant on, or associated with, many other molecular partners will simply not be functional if removed from their current context. This model is supported by bioinformatic analysis of HGT events in sequenced genomes. The second model, termed *the competition model*, argues instead that the two forms of reproduction (HGT and VGT) favor different genes in different environments. This model suggests that genes transit to horizontal reproduction when that mode of reproduction outpaces alleles of the same gene reproducing vertically. This model is supported by laboratory evolution experiments.

The complexity hypothesis posits that operational genes are more mobile than informational genes. Informational genes are those with products that are associated within large complexes and may be involved in such biochemical activities as transcription, translation, and replication. Operational genes, in contrast, may work alone or in very simple assemblies and thus more easily function after transfer. From six complete prokaryotic genomes that were analyzed for 132 orthologous genes, the dual contentions that gene transfer was a continuous process and that those genes most likely to introgress were operational were supported. Again, this analysis does not say how frequently genes are transferred, but how frequently different types of transferred genes transit into stable alien genes in new species.

The competition model differs from the complexity hypothesis for predicting the attributes of genes that make them transit to horizontal reproduction. It is based on the view that the current function of a protein is not sufficient to predict future roles in different environments. These roles in different environments, rather than in their cellular context alone, determine which genes transit from vertical to horizontal and back to vertical reproductive strategies.

The competition model is not at odds with the complexity hypothesis because it would accept that operational genes may more frequently, but not exclusively, enjoy a differential reproduction as mobile genes. Consistent with this expectation, there is bioinformatics evidence of informational gene transfers and even contemporary discoveries of plasmid vectors of informational genes. Interestingly, the mobility of these genes correlates with the relatively recent introduction of modern antibiotics by humans. In the case of the ribosomal S14 protein, there is compelling evidence that transfer and introgression may be facilitated by antibiotic pressure selecting for alleles of the *rps14* gene that could confer resistance. Likewise, the eukaryotic-type IleRS has been discovered on plasmids that deliver it to bacteria susceptible to the antibiotic mupirocin. Within the expectations of the competition model, these informational genes can have a role in some environments that makes them transit from a vertical to a horizontal reproductive strategy. The competition model goes further to explain how the

genes get mobilized, not just how transferred genes introgress.

A new study comparing the complete genomes of 116 prokaryotes supports the operational–informational division that is central to the complexity hypothesis. The huge amount of sequence information that makes up this study also revealed a second class of operational genes that are as immobile as the information genes. It also showed that among the genes most commonly found to be mobile were predominantly those associated with plasmids and phage, cell surface proteins, DNA binding (particularly restriction-modification), and pathogenicity. These categories include genes that are frequently classed as PSK, or postsegregational killing genes.

The distinction of PSK genes in this new study also provides tacit support for the competition model: PSK genes are defined as any combination of genes that simultaneously produce and suppress a toxic effect on the host. PSK genes attack other infectious elements, for example, competing plasmids and viruses, but do not necessarily increase the absolute rate of reproduction of the vector or the host. PSK genes have been found to be a significant disadvantage to vectors that are forced to reproduce at the rate of cell division. Only when PSK is coupled to HGT do the vectors bearing PSK genes demonstrate competitiveness with vectors that did not have such genes.

The PSK method of attack is to kill cellular offspring that lose the genes. If a bacterium is infected by an invading virus or an incompatible plasmid, the PSK genes kill the bacterium along with the invading horizontally mobile element. In doing so, the PSK-bearing vector does not benefit with an immediate increase in reproduction, but it does eliminate a competitor.

Antibiotic resistance, novel virulence determinants, and restriction-modification genes are likely to be PSK genes and thus have evolved in the same way. The structural and functional attributes of PSK are independent of the benefits such genes might provide the organismal host in the presence of antibiotics or other lethal agents. The advantages PSK genes confer upon the HGT vector are even more important than the cost to organismal hosts for carrying the genes.

PSK genes evolve by HGT, at least some of the time. However, these phenotypes are only indirectly related to how PSK genes, like antibiotic resistance, converted from chromosomal to horizontally transferred genes. Organisms with these genes may in time have found some use for them, explaining introgression, but that is not an explanation for how the genes came to evolve on horizontally mobile elements.

The competition model predicts that genes capable of causing cell death will, under the right circumstances, transit to horizontal reproduction. It is thus noted with some irony that classic PSK systems, also called *suicide genes*, have been recommended by a prominent panel of the US National Research Council as promising bioconfinement tools for application to genetically engineered microbes.

4 Barriers to HGT

If HGT were so common and frequent, why is there not more evidence of it? The definitive answer to this question is some ways off, because, as discussed above, the preponderance of searches for it so far

have been designed to detect introgression into organismal genomes. Toward the end of the last century, however, several groups independently started asking this question. Their motivation was not to discount HGT, but to yield biologically interesting hypotheses about the biological barriers to either transfer *or* introgression (Fig. 1).

There is no doubt that there is a raft of situations, circumstances, and processes that prevent or at least reduce the rate of HGT. These are referred to here as *transfer, inheritance, and introgression barriers.*

4.1 Transfer and Inheritance

Barriers to gene transfer and inheritance include those that prevent geographical access to genes, entry of genes into the cell or organism, stability of DNA (for example, restriction enzymes) and stability of integration (recombination and mismatch repair) or an inherent compatibility between important cis-acting replication sequences and the enzymes of replication.

Geographical barriers spatially separate species to an extent that prevents exposure to their respective genes. Entry barriers include impenetrable cell walls that prevent transformation or transduction, and differences in form (like flower shape) that prevent hybridization. Virus infectious ranges may be determined by the presence or absence of a specific receptor. The genetic material, whether it is protein, RNA or DNA, may be enzymatically degraded upon entry into a cell, or specially sequestered and denatured or depolymerized. Immediately following transfer and stabilization, the gene must replicate or, in the case of nucleic acids, physically recombine with a chromosome or other cellular replicon.

4.2 Introgression

Another layer of barriers may prevent introgression. Developmental barriers specifically deny incoming genes access to the germline. Genetic barriers prevent recombination (Sect. 2.1) or they prevent chromosome pairing during meiosis (Sect. 2.4). Selection barriers block the expansion of the recombinant genotype within the population or species. This can be due to the gene having no or a negative effect on host fitness or due to expression barriers.

Expression barriers arise from incompatibility of an alien gene or polypeptide product with the host expression biochemistry, roughly that referred to as the *central dogma reactions*. The central dogma reactions are well understood as individual processes and are summarized but are treated in depth elsewhere.

Failure of cis-acting sequences of alien genes or their transcripts or products, to be properly recognized or processed by any of the reactions between transcription and the proper placement of a mature protein may prevent the gene from providing a function that could make its new host differentially competitive. Regulatory sequences on alien genes may not effectively recruit specific transcription factors to bind to promoters, terminators, and enhancers. The alien gene may produce an mRNA that is spliced differently or not at all, or which requires special editing (Fig. 3). Translated polypeptides may not fold properly in the recipient or may not sort to the correct subcellular location.

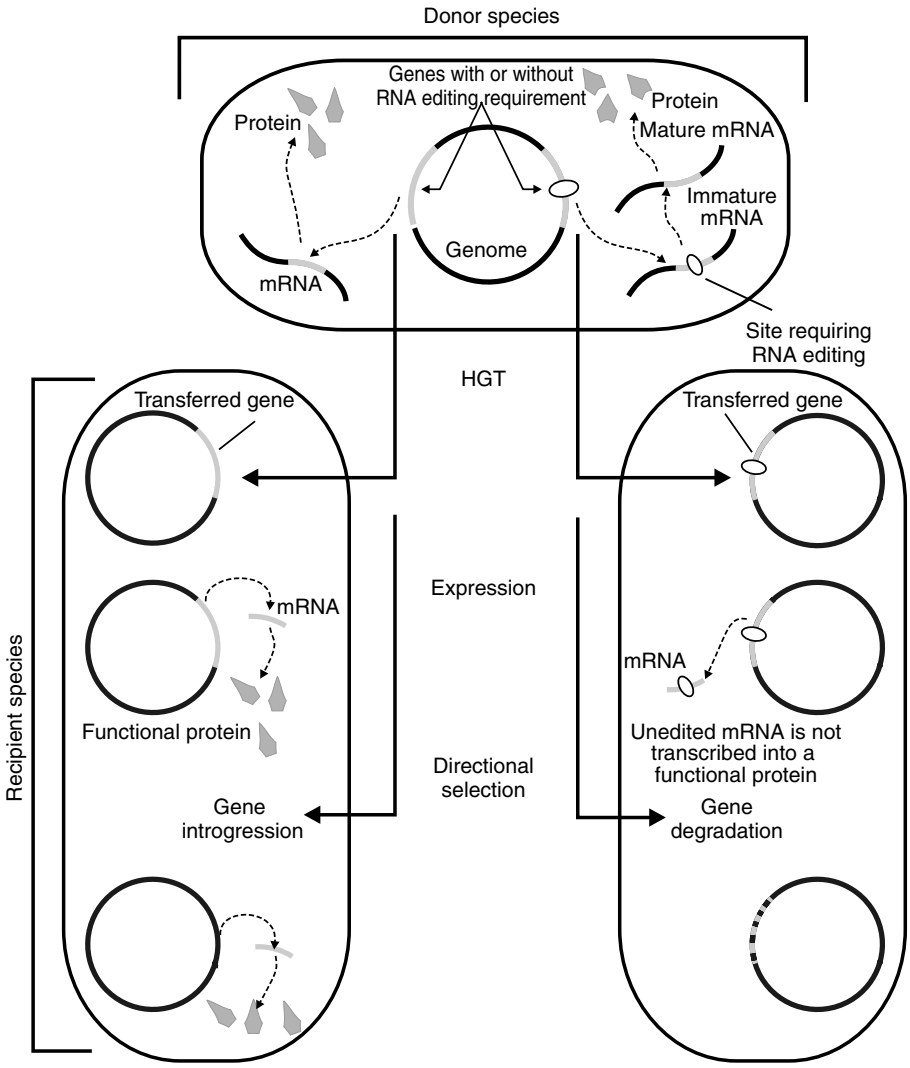

Fig. 3 RNA editing as an example of a molecular barrier to introgression. Symbols: rounded rectangles represent distinct donor or recipient species; circles represent genomes; arrows represent the linear sequence of events from HGT from donor to recipient genomes to the processes of gene expression and finally either intergression or gene degradation; protein mRNA strands and proteins are labeled as such. Some genes require donor-specific posttranscriptional RNA editing. Failure to edit transcripts could uncouple HGT from introgression if recipients do not have a similar RNA editing pathway. Genes without an RNA editing requirement are more likely to properly translate and may therefore introgress through directional selection.

5 Final Thoughts

The ultimate limitation of HGT is not transfer, but our ability to detect it. Gene transfers between closely related organisms may not be detected in genome sequences. While even small changes in existing genes may be important for function and introgression, they may be too small to distinguish from the noise of mutation through vertical descent. Small changes may arise by gene transfer and a combination of mutational amelioration and recombination, but these are almost always credited to repaired DNA damage and polymerase errors.

There are examples of genes that have overcome all the barriers to HGT described in Sect. 4. Of these barriers, only those that prevent transfer are fundamental to the evolution of all mobile genes. Barriers to inheritance and introgression only affect genes that tie their fates once again to the fate of an organism.

Keywords

Capacity Factor
The parameter used in HPLC to measure the retention of an analyte.

Capillary Column
This term refers to a chromatographic column of ''small'' diameter and is used in both gas and high-performance liquid chromatography. In HPLC, the term is usually applied to columns with internal diameters of between 0.1 and 2 mm. The term *microbore column* is often used synonymously to describe these columns but is more correctly applied to columns.

Gradient Elution
The changing of HPLC mobile phase composition during the course of an analysis.

high-performance liquid chromatography (HPLC)
A technology in which compounds are partitioned between a stationary medium and a flowing liquid phase in a tubular format under high pressure, resulting in the separation of a mixture of components and the reproducible time of elution of each specific compound.

Ion Trap Mass Spectrometer
This device consists of two end-cap electrodes (entrance and exit) and a ring electrode. An ion trap mass spectrometer separates ions based on mass-to-charge ratio (m z^{-1}).

Once ions are introduced into the ion trap mass spectrometer, the radiofrequency (rf) amplitude is increased so that ions are sequentially ejected (by increasing mass) and detected.

Isocratic Elution
The use of a mobile phase of constant composition during the course of an analysis.

Mobile Phase
That part of a chromatographic system that causes the analyte to move from the point of injection to the detector – in HPLC, this is a liquid.

Peak Capacity
The number of peaks that can be separated within a defined separation or gradient time.

Peptide Mapping
The process of considering the amino acid sequence information from peptides obtained by enzyme digestion in an attempt to derive the (amino acid) sequence of the parent protein.

Resolution
A term that indicates the ability of a device/technique to separate/distinguish between closely related signals. In chromatography, it relates to the ability to separate compounds with similar retention characteristics, and in mass spectrometry it relates to the ability to separate ions of similar m/z ratios.

Stationary Phase
That part of the chromatographic system with which the analytes interact, over which the mobile phase flows.

HPLC is extremely versatile for the isolation of peptides and proteins from a wide variety of synthetic or biological sources. The complexity of the mixture to be chromatographed will depend on the nature of the source and the degree of preliminary clean up that can be performed. In the case of synthetic peptides, RPC is generally employed both for the initial analysis and the final large-scale purification. The isolation of proteins from a biological cocktail, however, often requires a combination of techniques to produce a homogenous sample. HPLC techniques are then introduced at the later stages following initial precipitation, clarification and preliminary separations using soft gel. Purification protocols therefore need to be tailored to the specific target molecule.

This chapter deals with the different HPLC techniques that are commonly employed for the analysis and purification of peptides and proteins. A brief overview of the theory of each mode of chromatography will be presented and then discussed

in terms of the parameters that control resolution and illustrated with relevant examples. The interested reader is also referred to a number of recent publications that provide a comprehensive theoretical and practical overview of this topic.

1 Introduction

The introduction of high-performance liquid chromatography (HPLC) to the analysis of peptides and proteins some 25 years ago revolutionized the biological sciences by enabling the rapid and sensitive analysis of peptide and protein structure in a way that was inconceivable 30 years ago.

Today, HPLC in its various modes has become the pivotal technique in the characterization of peptides and proteins and has therefore played a critical role in the development of peptide and protein-based pharmaceuticals. The extraordinary success of HPLC can be attributed to a number of factors. These include (1) the excellent resolution that can be achieved under a wide range of chromatographic conditions for very closely related molecules as well as structurally quite distinct molecules; (2) the experimental ease with which chromatographic selectivity can be manipulated through changes in mobile phase characteristics; (3) the generally high recoveries and hence high productivity and (4) the excellent reproducibility of repetitive separations carried out over a long period of time, which is due partly to the stability of the sorbent materials under a wide range of mobile phase conditions.

Reversed phase chromatography (RPC) is by far the most commonly used mode of separation for peptides, although ion-exchange (IEC) and size exclusion (SEC) chromatography also find application. The three-dimensional structure of proteins can be sensitive to the often harsh conditions employed in RPC, and as a consequence, RPC is employed less for the isolation of proteins where it is important to recover the protein in a biologically active form. IEC and SEC affinity chromatography are therefore the most commonly used modes for proteins, but RPC and hydrophobic interaction (HIC) chromatography are also employed.

2 Theoretical Considerations

An appreciation of the factors that control the resolution of peptides and proteins in interactive modes of chromatography can assist in the development and manipulation of separation protocols to obtain the desired separation. The capacity factor k' of a solute can be expressed in terms of the retention time t_r, through the relationship

$$k' = (t_r - t_o)/t_o \qquad (1)$$

where t_0 is the retention time of a nonretained solute. The practical significance of k' can be related to the selectivity parameter α, defined as the ratio of the capacity factors of two adjacent peaks as follows

$$\alpha = k'_i/k'_j \qquad (2)$$

which allows the definition of a chromatographic elution window in which retention times can be manipulated to maximize the separation of components within a mixture.

The optimization of high-resolution separations of peptides and proteins involves the separation of sample components through manipulation of both retention times and solute peak shape. The second factor that is involved in defining the quality of a separation is therefore the peak width σ_t. The degree of peak broadening is directly related to the efficiency of the column and can be expressed in terms of the number of theoretical plates, N, as follows

$$N = (t_r)^2/{\sigma_t}^2 \quad (3)$$

N can also be expressed in terms of the reduced plate height equivalent h, the column length L and the particle diameter of the stationary phase material d_p, as

$$N = hL/d_p \quad (4)$$

The resolution, R_s, between two components of a mixture therefore depends on both selectivity and bandwidth according to

$$R_s = 1/4\sqrt{N}(\alpha - 1)[1/(1 + k')] \quad (5)$$

This equation describes the relationship between the quality of a separation and the relative retention, selectivity and the bandwidth and also provides the formal basis upon which resolution can be manipulated to achieve a particular level of separation. Thus, when faced with an unsatisfactory separation, the aim is to improve resolution by one of three possible strategies: the first is to increase α, the second is to vary k' within a defined range normally $1 < k' < 10$, or thirdly to increase N, for example, by using very small particles in narrow bore columns.

The challenge facing the scientist who wishes to analyze and/or purify their peptide or protein sample is the selection of the initial separation conditions and subsequent optimization of the appropriate experimental parameters. This chapter provides an overview of the different techniques used for the analysis and purification of peptides and proteins and the experimental options available to achieve a high-resolution separation of a peptide or protein mixture.

3 Reversed Phase Chromatography

RPC is now an indispensable tool for the high-performance separation of complex mixtures of peptides and proteins and is used for both analytical and preparative applications. Analytical applications range from the assessment of purity of peptides following solid-phase peptide synthesis, to the analysis of tryptic maps of proteins. Preparative RPC is also used for the micropurification of protein fragments for sequencing to large-scale purification of synthetic peptides. An example of the high-resolution analysis of a tryptic digest of a protein is shown in Fig. 1. This figure, in which 150 peaks were identified, demonstrates the highly selective separation that can be achieved with enzymatic digests of proteins using RPC as part of the quality control or structure determination of a recombinant or natural protein. The chromatographic separation was obtained with a C2/C18 stationary phase packed in a column of dimensions 10 cm × 4.6 mm internal diameter (ID). Separated components can then be directly subjected to further analysis such as automated Edman N-terminal sequencing or electrospray mass spectrometry.

The purification of synthetic peptides usually involves an initial separation on an analytical scale to assess the complexity of the mixture followed by large-scale

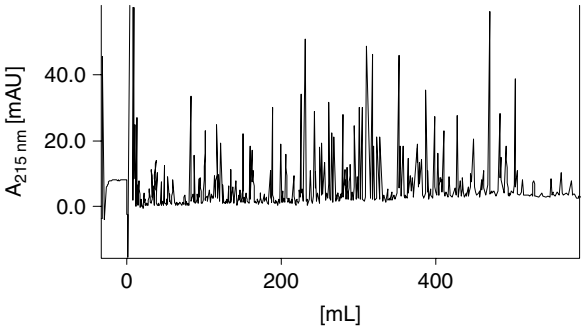

Fig. 1 High-resolution reversed phase chromatographic separation of a tryptic digest of a 165-kDa protein on a μRPC C2/C18 ST 4.6/100 column, (dimensions 10 cm × 4.6 mm ID, 3-μm particle size, 12-nm pore size). Eluent A: 0.065% trifluoroacetic acid (TFA) in water, eluent B: 0.050% TFA in 84% acetonitrile. Gradient elution was carried out with 0% B for 2 column volumes (CV), 0 to 50% for 392 CV (650 min); 50 to 100% B for 55 CV (91 min); 100% B for 10 CV (17 min), flow rate of 1 mL min^{-1} and detection was at 215 nm (Reprinted with permission from Amersham Bioscience, AKTA™ purifier Application Note No. 18-1119-53).

purification and collection of the target product. A sample of the purified material can then be subjected to RPC analysis under different elution conditions to check for purity.

The extensive use of RPC for the purification of peptides, small polypeptides with molecular weights up to 10 000 Da, and related compounds of pharmaceutical interest has not been replicated to the same extent for larger polypeptides (MW > 10 000 Da) and globular proteins. The combination of the traditionally used acidic buffering systems and the hydrophobicity of the *n*-alkylsilica supports, which can result in low mass yields or the loss of biological activity of larger polypeptides and proteins, have often discouraged practitioners from using RPC methods for large-scale protein separations. The loss of biological activity, the formation of multiple peaks for compositionally pure samples and poor yields of protein can all be attributed to the denaturation of protein solutes during the separation process using RPC. While these features detract from the use of RPC as a technique of choice in preparative purification protocols with proteins, these same characteristics can provide a unique opportunity to study protein folding and stability. Thus, the widespread practical application of RPC has been recently accompanied by a significant improvement in our understanding of the molecular basis of the retention process and its impact on conformational stability of both peptides and proteins. As a result, RPC can now also be used as a tool for the analysis of the interacting behavior of peptides and proteins at hydrophobic surfaces.

3.1 Basic Principles

The mechanism by which peptides and proteins are retained in RPC involves the hydrophobic expulsion of the solute

from the polar mobile phase followed by adsorption onto a nonpolar sorbent. Peptides and proteins are thus retained to different extents depending on their surface hydrophobicity, the eluotropicity of the mobile phase, and the nature of the hydrophobic ligands.

The physicochemical basis of RPC lies in the hydrophobic interaction between a peptide or protein and the hydrophobic matrix, and can be described in terms of the solvophobic theory where the isocratic retention factor can be expressed as

$$\ln k' = \log k_o - (N\Delta A_h + 4.836N^{1/3} \times [\kappa^e - 1]V^{2/3})\gamma/RT \quad (6)$$

where N is Avogadro's number, ΔA_h is the hydrophobic contact area of the interacting solute and γ is the surface tension of the mobile phase. The parameter κ^e is the ratio of the energy required to create a cavity for a solvent molecule and the energy required to extend the planar surface of the liquid by the surface area of the solute molecule. Thus, simply stated, elution in RPC is achieved through a decrease in the microscopic surface tension associated with the solute–sorbent interface. Experimentally this is achieved through changes in the water content by variation in the mole fraction of organic solvent in RPC. However, peptides and proteins are generally separated by gradient elution conditions. Under these conditions, the experimentally observed retention data can be analyzed according to the linear solvent strength model (LSS) as follows

$$\log \overline{k} = \log k_o - S\overline{\varphi} \quad (7)$$

where $\overline{k}$ is the solute median capacity factor, and $\overline{\varphi}$ is the corresponding organic mole fraction. The log k_0 value is the affinity of the solute for the sorbent in the absence of organic solvent. By analogy with the solvophobic equation above, the S-value is related to the hydrophobic contact region established between the solute and the sorbent surface. Both S and log k_0 can be derived from plots of log $\overline{k}$ versus $\overline{\varphi}$ and the LSS model provides the computational basis for the rational optimization of peptide and protein separations. An example of these plots is shown in Fig. 2 for a series of peptide analogs related to neuropeptide Y-[18–36], which differ in sequence only by the substitution of a single D-amino acid residue. These plots illustrate the ability

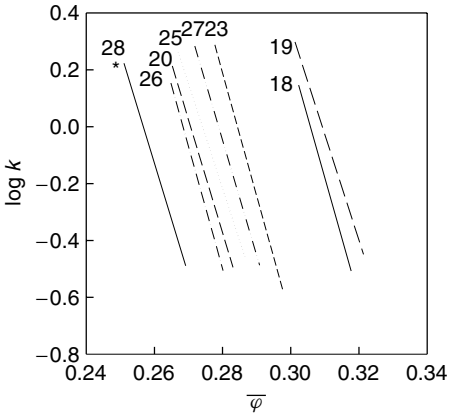

Fig. 2 Plots of log $\overline{k}$ versus $\overline{\varphi}$ for a series of D-analogs of neuropeptide Y-[18–36] separated on C18 silica with acetonitrile as the organic modifier at 4 °C. Column: Bakerbond (J T Baker, Phillipsburg, NJ) RP-C18, 25 cm × 4.6 mm ID, 5-µm particle size, 30-nm pore size. The retention plot for each analog is designated by the residue position of the D-amino acid substitution. The plots were derived from best-fit analysis to the data points (Reprinted with permission from Lazoura, E. et al. (1997) Conformational analysis of neuropeptide Y-[18–36] analogs. . ., *Biophys. J.* **72**, 238–46).

of RPC to resolve very small differences in peptide structure and also illustrate how RPC can act as a molecular probe of peptide surface topography. The data presented in these plots also provide a clear example of how to optimize separations, whereby maximal optimization will be achieved by selecting elution conditions where there is the greatest separation between the retention plots. The elution profiles of five of the NPY-[18–36] analogs are shown in Fig. 3 and demonstrate that the order of elution of the peaks corresponds to the relative position of the retention plots shown in Fig. 2 and also illustrates the corresponding degree of resolution that is obtained.

Peptides and proteins are retained in RPC through hydrophobic interactions. As depicted in Fig. 4(a), the contact region for small peptides involves the contribution from all or a large proportion of the peptide structure. As a consequence, the retention time for small peptides can be predicted on the basis of the amino acid composition through summation of the hydrophobicity coefficients for the constituent amino acid residues. In contrast, it has been well established that proteins interact with the chromatographic surface in an orientation-specific manner, in which their retention time is determined by the molecular composition of specific contact regions. For larger polypeptides and proteins that adopt a significant degree of secondary and tertiary structure, there is no correlation between retention times and the summated hydrophobicity coefficients of all constituent amino acid residues. In these cases, the chromatographic contact region comprises a small proportion of the total molecular surface as shown in Fig. 4(b, c).

3.2 Factors Influencing Retention in RPC

3.2.1 Stationary Phases

The most commonly employed experimental procedure for the RPC analysis of peptides and proteins generally involves the use of an octadecylsilica-based sorbent and a mobile phase. The chromatographic packing materials that are generally used are based on microparticulate porous silica, which allows the

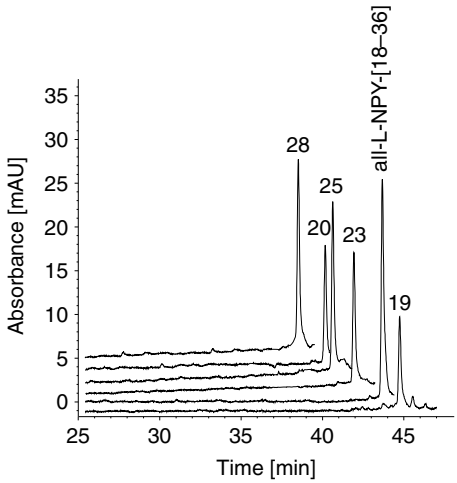

Fig. 3 Chromatograms showing the separation of the all-L-NPY-[18–36] peptide and NPY-[18–36]- analogs with D-substitutions at positions 19, 20, 23, 25, and 28 separated on a C18 silica (Bakerbond, J T Baker, Phillipsburg, NJ) RP-C18, 25 cm × 4.6 mm ID, 5-µm particle size, 30-nm pore size) with a 60-min gradient from 0 – to 50% acetonitrile at 1 mL min^{-1}. The separation was used to derive the retention plots shown in Fig.2 (Reprinted with permission from Lazoura, E. et al. (1997) The conformational analysis of NPY-[18–36] analogues of hydrophobic surfaces, *Biophys. J.* **72**, 238–46).

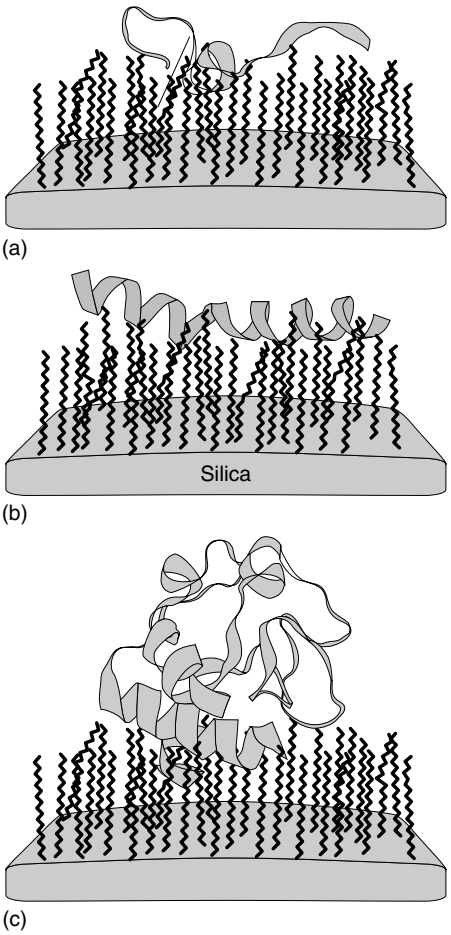

Fig. 4 Schematic representation of the binding of a polypeptide to an interactive chromatographic sorbent. The shaded areas on the polypeptide indicate the chromatographic contact region, which will be defined by the nature of the sorbent material. In reversed phase and hydrophobic interaction chromatography, the areas will be hydrophobic while in ion-exchange chromatography, the contact regions will represent the surface regions of highest charge density.

use of high linear-flow velocities resulting in favorable mass transfer properties and rapid analysis times. The silica is chemically modified by a derivatized silane bearing an *n*-alkyl hydrophobic ligand. The most commonly used ligand is *n*-octadecyl (C18), while *n*-butyl (C4) and *n*-octyl (C8) also find important application, and phenyl and cyanopropyl ligands can provide different selectivity. The process of chemical immobilization of the silica surface results in approximately half of the surface silanol group being modified. The sorbents are therefore generally subjected to further silanization with a small reactive silane to produce an end-capped packing material. The type of *n*-alkyl ligand significantly influences the retention of peptides and proteins and can therefore be used to manipulate the selectivity of peptide and protein separations. While the detailed molecular basis of the effect of ligand structure is not fully understood, a number of factors including the relative hydrophobicity and ligand chain length, flexibility and the degree of exposure of surface silanols all play a role in the retention process. An example of the effect of chain length on peptide separations can be seen in Fig. 5. It can be seen that the peaks labeled T_3 and T_{13} are fully resolved on the C4 packing but cannot be separated on the C18 material. In contrast, the peptides T_5 and T_{18} are unresolved on the C4 column but fully resolved on the C18 material. In addition to the effect on peptide selectivity, the choice of ligand type can also influence protein recovery and conformational integrity of protein samples. Generally, higher protein recoveries are obtained with the shorter and less hydrophobic *n*-butyl ligands. However, proteins have also been obtained in high yield with *n*-octadecyl silica.

The denaturation of proteins by RPC sorbents can also be controlled by using silica that has been coated with

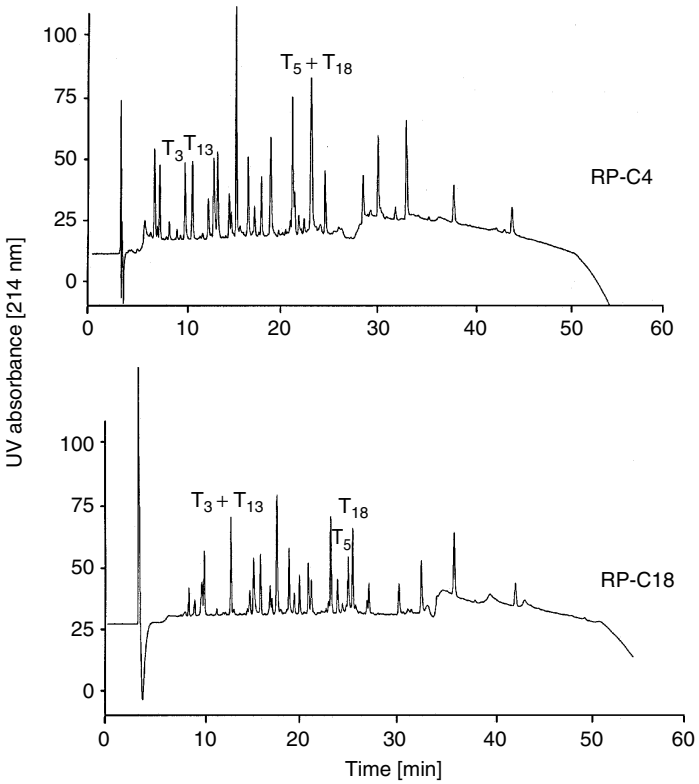

Fig. 5 The influence of *n*-alkyl chain length on the separation of tryptic peptides derived from porcine growth hormone. Top: Bakerbond (J T Baker, Phillipsburg, NJ) RP-C4, 25 cm × 4.6 mm ID, 5 µm-particle size, 30-nm pore size. Bottom: Bakerbond (J T Baker, Phillipsburg, NJ) RP-C18, 25 cm × 4.6 mm ID, 5-µm particle size, 30-nm pore size. Conditions, linear gradient from 0 to 90% acetonitrile with 0.1% TFA over 60 min, flow rate of 1 mL min^{-1}, 25 °C (Reprinted with permission from Aguilar, M-I., Hearn, M.T.W. (1996) High resolution reversed phase high performance liquid chromatography of peptides and proteins, *Methods Enzymol.* **270**, 3–26).

polymethacrylate-based polymers, which provide a series of sorbents with varying surface hydrophobicity, and in which the surface silanol groups have been masked. Silica-based packings are also susceptible to cleavage at pH values greater than 7. This limitation can severely restrict the utility of these materials for separations that require basic pH conditions to effect resolution. In these cases, alternative stationary phases have been developed including cross-linked polystyrene divinylbenzene and porous zirconia, which are all stable to hydrolysis at alkaline pHs.

The geometry of the particle in terms of the particle diameter and pore size is also an important feature of the packing material. As predicted by Eq. 4, improved resolution can be achieved by decreasing the particle diameter d_p. The most commonly used range of particle diameters for analytical scale RPC is 3 to

5 μm. There are also examples of the use of nonporous particles of smaller diameter. For preparative scale separations, 10 to 20 μm particles are utilized. The pore size of RPC sorbents is also an important factor that must be considered. For peptides, the pore size generally ranges between 100 to 300 Å depending on the size of the peptides. Porous materials of ≥300 Å pore size are necessary for the separation of proteins, as the solute molecular diameter must be at least one-tenth the size of the pore diameter to avoid restricted diffusion of the solute and to allow the total surface area of the sorbent material to be accessible. The recent development of particles with 6000 to 8000 Å pores with a network of smaller pores of 500 to 1000 Å has also allowed very rapid protein separations to be achieved.

3.2.2 Mobile Phases

One of the most powerful characteristics of RPC is the ability to manipulate solute retention and resolution through changes in the composition of the mobile phase. In RPC, peptide and protein retention is due to multisite interactions with the ligands. The practical consequence of this is that high-resolution isocratic elution of peptides and proteins can rarely be achieved as the experimental window of solvent concentration required for their elution is very narrow. Mixtures of peptides and proteins are therefore routinely eluted by the application of a gradient of increasing organic solvent concentration. RPC is generally carried out with an acidic mobile phase, with trifluoroacetic acid (TFA), the most commonly used additive due to its volatility. Phosphoric acid, perchloric acid, formic acid, hydrochloric acid, acetic acid, and heptafluorobutyric acid have also been used. The effect of ion-pairing reagents on peptide separation is illustrated in Fig. 6 for a series of peptide standards separated on a C18 column. Alternative additives such as nonionic detergents can be used for the isolation of more hydrophobic proteins such as membrane proteins.

The three most commonly employed organic solvents are acetonitrile, methanol, and 2-propanol, which all exhibit high optical transparency in the detection wavelengths used for peptide and protein analysis. Acetonitrile provides the lowest viscosity solvent mixtures and 2-propanol is the strongest eluent. An example of the influence of organic solvent where changes in selectivity can be observed for a number of peptide peaks in the tryptic map is shown in Fig. 7. In addition to the eluotropic effects, the nature of the organic solvent can also influence the conformation of both peptides and proteins and will therefore have an additional effect on selectivity through changes in the structure of the hydrophobic contact region. In the case of proteins, this may also impact on the level of recovery of biologically active material.

3.2.3 Column Geometry

The desired level of efficiency and sample loading size determines the dimension of the column to be used. For small peptides and proteins, increased resolution will be obtained with increases in column length. Thus, for applications such as tryptic mapping, column lengths between 15 to 25 cm and internal diameter (ID) of 4.6 mm are generally employed. However, for larger proteins, low mass recovery and loss of biological activity may result with these columns due to irreversible binding and/or denaturation. In these cases, shorter columns of between 2 and 20 cm in length can be used. For preparative applications in the 1 to 500 mg scale, such as the purification of synthetic peptides, so-called

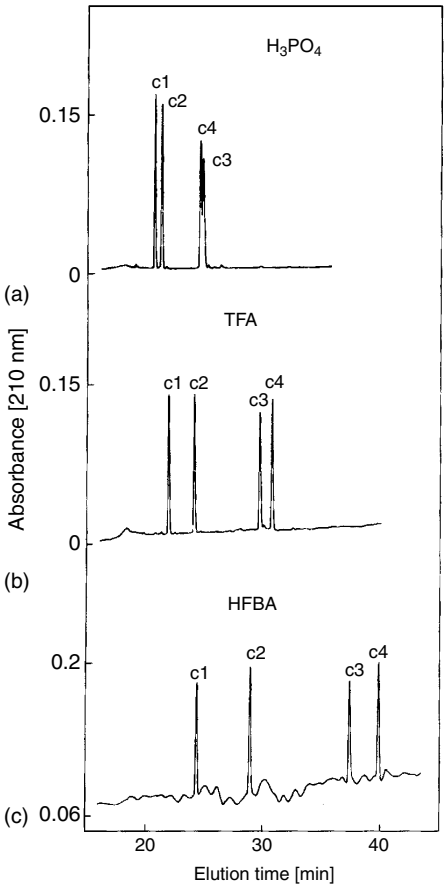

Fig. 6 The influence of ion-pairing reagent on the separation of a mixture of synthetic peptides in reversed phase chromatography using a SynChropak C18, 25 cm × 4.6 mm ID, 6.5-μm particle size, 30-nm pore size (SynChrom, Linden, IN). Conditions: linear gradient from 0 to 100% acetonitrile containing A. 0.1%H_3PO_4; B, 0.1% TFA; and C; 0.1% HFBA; flow rate of 1 mL min^{-1}, 26 °C. Peptide sequences:
C1 = Ac-GGGLGGAGGLK-amide,
C2 = Ac-KYGLGGAGGLK-amide.
C3 = Ac-GGALKALKGLK-amide,
C4 = Ac-KYALKALKGLK-amide
(Reprinted with permission from Mant, C.T., Hodges, R.S. (Eds.) (1991) *High Performance Liquid Chromatography of Peptides and Proteins: Separation, Analysis and Conformation*, CRC Press, Boca Raton, FL, pp. 327–41).

semipreparative columns of dimensions 30 cm × 1 cm ID and preparative columns of 30 cm × 2 cm ID can be used.

The selection of the internal diameter of the column is based on the sample capacity and detection sensitivity. While most analytical applications are carried out with columns of internal diameter of 4.6-mm ID (as shown in Figs. 1, 3, and 5), for samples derived from previously unknown proteins where there is a limited supply of material, the task is to maximize the detection sensitivity. In these cases, narrow bore columns of 1- or 2-mm ID can be used, which allows the elution and recovery of samples in much smaller volumes of solvent. Capillary chromatography (see Sect. 7 below) is also finding increasing application where capillary columns of ID between 0.2 to 0.4 mm and column length of 15 cm result in the analysis of fmole of sample as shown in Fig. 8. The effect of decreasing column internal diameter on detection sensitivity is shown in Fig. 9 for the analysis of lysozyme on a C18 material packed into columns of 4.6-, 2.1-, and 0.3-mm ID.

3.2.4 Operating Parameters

There are several operating parameters that can be changed in order to manipulate

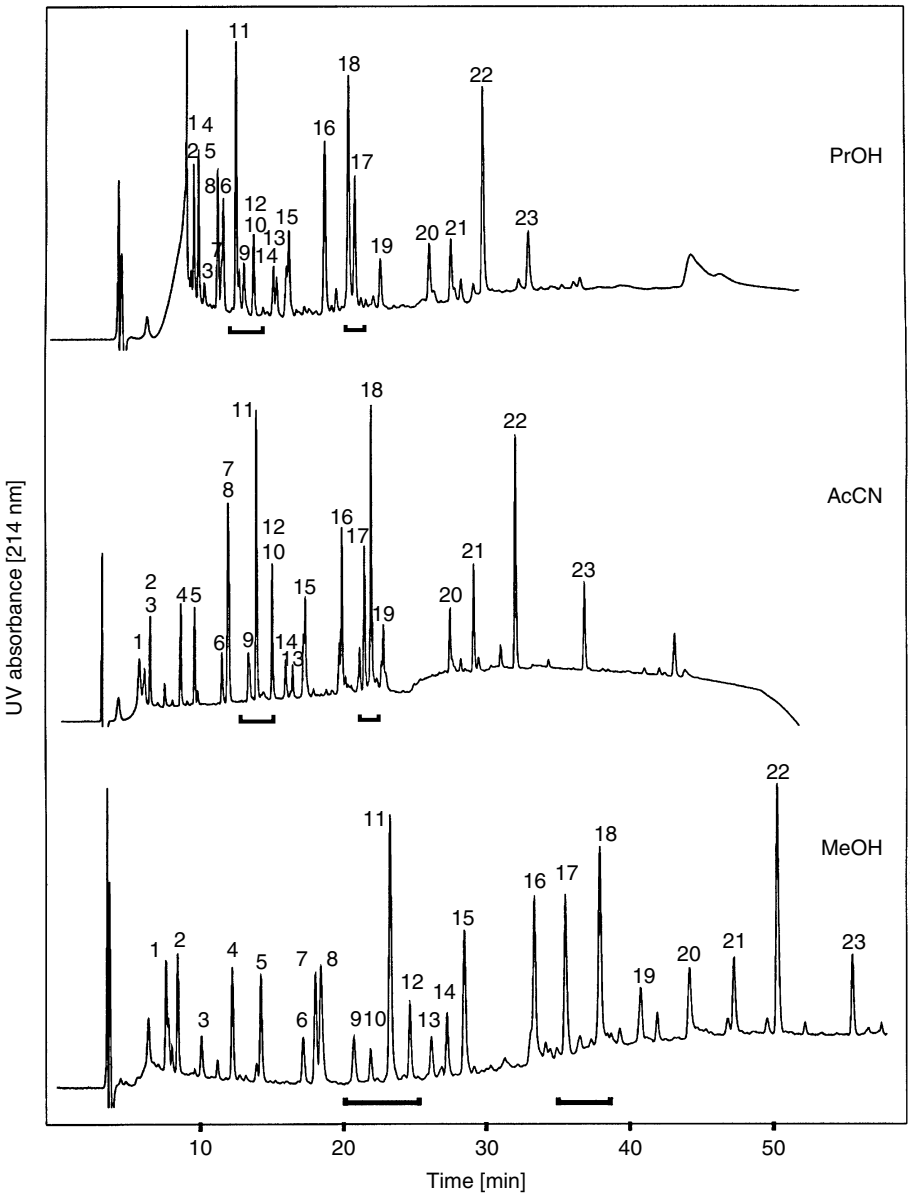

Fig. 7 The influence of organic solvent on the reversed phase chromatography of tryptic peptides derived from porcine growth hormone. Column: Bakerbond (J T Baker, Phillipsburg, NJ) RP-C4, 25 cm × 4.6 mm ID, 5-µm particle size, 30-nm pore size. Conditions, linear gradient from 0 to 90% 2-propanol (top), acetonitrile (middle) or methanol (bottom) with 0.1% TFA over 60 min, flow rate of 1 mL min^{-1}, 25 °C (Reprinted with permission from Aguilar, M-I., Hearn, M.T.W. (1996) *Methods Enzymol.* **270**, 3–26).

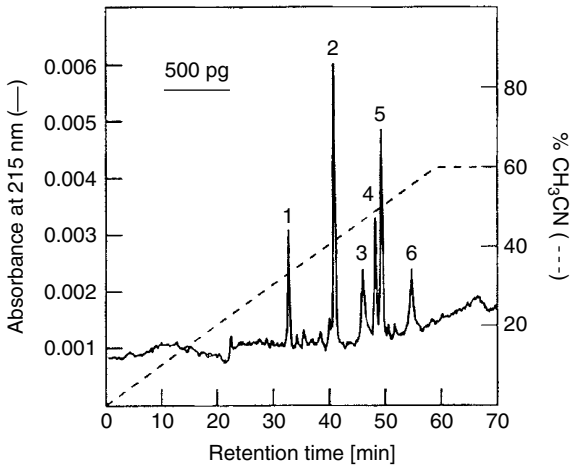

Fig. 8 The separation of proteins by reversed phase capillary chromatography. Column; Brownlee RP-300, 15 cm × 0.2 mm ID, 5-µm particle size, 30-nm pore size. Conditions; linear gradient from 0 to 60% acetonitrile over 60 min, flow rate of 1.4 µL min^{-1}. Protein; 1 = ribonuclease B, 2 = lysozyme, 3 = bovine serum albumin, 4 = carbonic anhydrase, 5 = myoglobin, 6 = ovalbumin (Reprinted with permission from Moritz, R.L., Simpson, R.J. (1993) in: Imahori, K., Sakiyama, F. (Eds.) *Methods in Protein Sequence Analysis*, Plenum Press, New York, pp. 3–10).

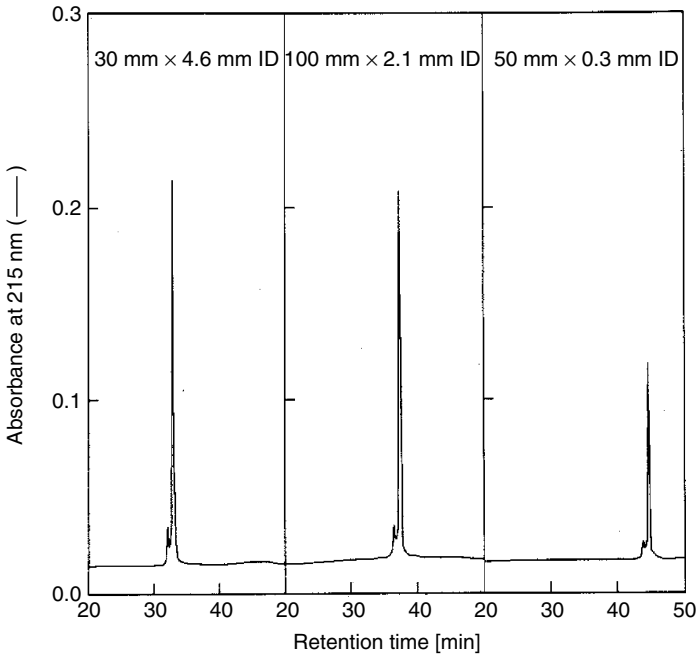

the resolution of peptide and protein mixtures in RPC. These parameters include the gradient time, the gradient shape, the mobile phase flow rate, and the operating temperature. The typical experiment with an analytical scale column would utilize a linear gradient from 5% organic solvent up to between 50 to 100% solvent over a time range of 20 to 120 min while flow rates are between 0.5 to 2.0 mL min^{-1}. With microbore columns [1–2 mm ID] flow rates of 50 to 250 µL min^{-1} are used, while for capillary columns of 0.2- to 0.4-mm ID, flow rates of 1 to 4 µL min^{-1} are applied. At the preparative end of the scale with columns of 10- to 20-mm ID, flow rates between 5 to 20 mL min^{-1} are required.

The choice of gradient conditions will depend on the nature of the molecules of interest. The influence of gradient time on the separation of a series of ribosomal proteins is shown in Fig. 10. Generally, the use of longer gradient times provides improved separation. However, these conditions also increase the residence time of the peptide or protein solute at the sorbent surface, which may then result in an increase in the degree of denaturation.

The operating temperature can also be used to manipulate resolution. While the separation of peptides and proteins is normally carried out at ambient temperature, solute retention in RPC is influenced by temperature through changes in solvent

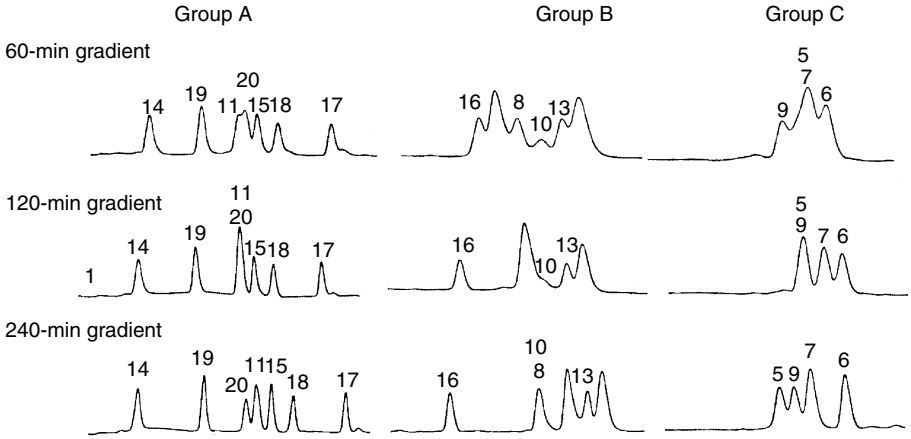

Fig. 10 The effect of gradient time on the resolution of ribosomal proteins by reversed phase chromatography. Column: Du Pont Bioseries Protein PLUS. Conditions: 25 to 46% acetonitrile with 0.1% triethylamine and 0.042% TFA, over 60 min (top), 120 min (middle) or 240 min (bottom), at a flow rate of 0.7 mL min^{-1} (Reprinted with permission from Ghrist, B.F.D. et al. Column: Brownlee RP-300 C8 (7 µm particle size, 30 nm pore size), 3 cm × 4.6 mm ID and 10 cm × 2.1 mm ID (Applied Biosystems) and 5 cm × 0.32 mm ID. Conditions: linear gradient from 0 to 60% acetonitrile with 0.1% TFA over 60 min, 45 °C. Flow rates, 1 mL min^{-1}, 200 µL min^{-1} and 4 µL min^{-1} for the 4.6-, 2.1-, and 0.32-mm ID columns, respectively. Sample loadings, lysozyme, 10, 4, and 0.04 µg for the 4.6-, 2.1-, and 0.32-mm ID columns respectively. (Reprinted from Moritz, R.L., Simpson, R.J. (1992) *J. Chromatogr.* **646**, 53–65, with kind permission from Elsevier Science – NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands).

viscosity. In addition to this, peptide and protein conformation can also be manipulated by temperature. In the case of proteins, where biological recovery is not important, increasing temperature can be used to modulate retention via denaturation of the protein structure. For peptides, it has been shown that secondary structure can actually be enhanced through binding to the hydrophobic sorbent. Changes in temperature can therefore also be used to manipulate the structure and retention of peptide mixtures.

Chromatographic recovery of proteins from polyacrylamide gels is another important application of RPC. Inverse gradient elution chromatography has been successfully utilized for the micropreparative isolation of proteins from SDS-PAGE electroeluates. This approach is based on observations that certain RPC packings display strong interactions with proteins at high organic solvent concentrations. This allows the loading of the electroeluate under conditions where the protein is retained while the SDS and other gel-related contaminants are washed through the column. The protein is then recovered in high yield by a gradient of decreasing organic solvent.

Detection of peptides and proteins in RPC, and in all modes of chromatography, generally involves detection at between 210 to 220 nm, which is specific for the peptide bond, or at 280 nm, which corresponds to the aromatic amino acids tryptophan and tyrosine. The use of photodiode array detectors can enhance the detection capabilities by the on-line accumulation of complete solute spectra. The spectra can then be used to identify peaks specifically on the basis of spectral characteristics and for the assessment of peak purity. In addition, second derivative spectroscopy can provide information on the conformational integrity of proteins following elution.

In summary, RPC is now firmly entrenched as the central tool for the analysis of peptides and proteins and thus plays a pivotal role in the pharmaceutical industry providing the core analytical technique at all stages of the development of peptide and protein-based therapeutics.

4
Hydrophobic Interaction Chromatography

Hydrophobic interaction chromatography (HIC) is a valuable technique for the separation of proteins under nondenaturing conditions. HIC involves the use of high salt concentrations to promote hydrophobic interactions between the protein and the hydrophobic stationary phase. Solutes are then eluted in order of increasing hydrophobicity through the application of a descending salt gradient that weakens the hydrophobic interactions between the protein and the sorbent material. The ligands used for HIC materials are less hydrophobic than those in RPC. Thus, in contrast to the denaturing effects of low pH and organic solvent present in RPC systems, the mobile phases used in HIC generally stabilize the protein structure.

4.1
Basic Principles

The primary factors that control protein retention in HIC are similar to those factors that contribute to retention in RPC, that is, the surface tension of the mobile phase and the exposed hydrophobic surface area of the protein solute. The use of the solvophobic theory has been extended to describe the effects of neutral salts on protein solubility and retention

in HIC. In particular, the dependence of the logarithmic capacity factor on salt concentration m, can be expressed as

$$\log k' = \log k_0 + [(-D\mu + \upsilon + N\Delta A_h\sigma)m]/RT \quad (8)$$

where $D\mu$ and υ are terms related to the dielectric constant of the medium and the protein dipole moment. Thus, retention in HIC is dependent on the contact surface area ΔA_h, established between the solute and the sorbent and the molal surface tension increment σ of the eluting salt solution. Selectivity optimization in HIC therefore involves changes in protein solubility characteristics through either changes in the structure of the stationary phase ligand or changes in the mobile phase characteristics through the use of salts of different molal surface tension increments. A linear relationship between the capacity factor of a protein and the corresponding salt concentration is generally observed and Eq. 8 can be simplified to

$$\log k' = \lambda m + C \quad (9)$$

where C incorporates all the salt-independent terms and λ is the slope of plots of log k' versus salt concentration, m. The linear dependence of protein retention on salt concentration for a series of globular proteins is illustrated in Fig. 11. The term λ has also been shown to be linearly related to the protein surface area and the molal surface tension increment, which is consistent with the predictions of Eq. 8.

4.2 Factors Influencing Retention in HIC

4.2.1 Stationary Phase

Both polymeric and silica-based HIC supports have been produced and a range of mildly hydrophobic ligands are available to perform HIC. In particular, both alkyl and aryl ligands have proven to be successful in obtaining high levels of selectivity. Figure 12 shows the influence of a range

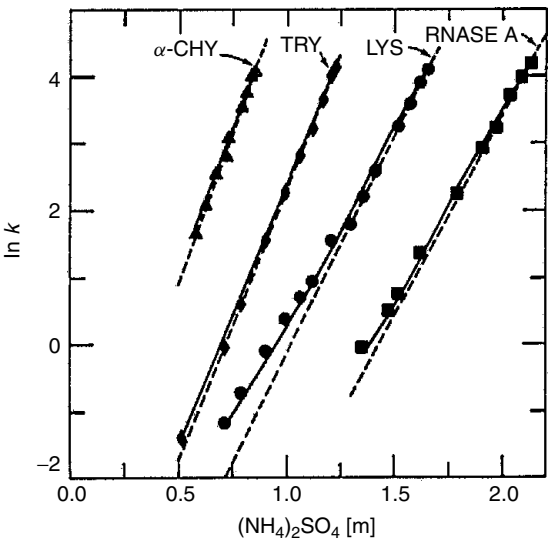

Fig. 11 The dependence of log k' on ammonium sulfate concentration for a series of proteins separated by HIC during isocratic elution. Column; TSK-phenyl (Toyo Soda). Conditions: 50 mM phosphate buffer, pH 7, flow rate 3 mL min^{-1}, 45 °C. (1987) *Chromatographia* **24**, 646–650).

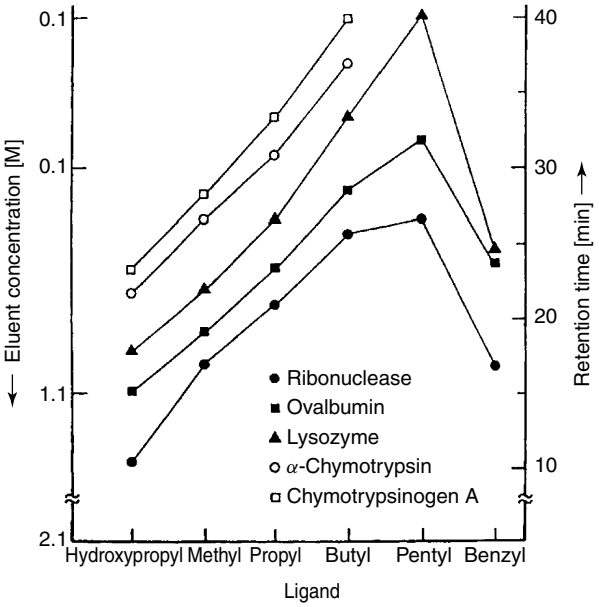

Fig. 12 The effect of ligand type on the elution of proteins in hydrophobic interaction chromatography. Column: SynChropak hydroxypropyl, propyl, methyl, butyl, pentyl and benzyl columns, 25 cm × 4.6 mm ID, 6.5-μm particle size, 30-nm pore size (SynChrom, Linden, IN). Conditions; linear gradient from 2-0M ammonium sulphate in 0.1M potassium phosphate, pH 6.8, over 30 min at a flow rate of 1 mL min^{-1}. (Reprinted from Gooding, D.L. et al. (1986) Optimization of preparative hydrophobic interaction chromatographic purification methods, *J. Chromatogr.* **359**, 331–37, with kind permission from Elsevier Science – NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands).

of ligands on the retention behavior of a series of globular proteins and demonstrates that protein retention increases in the order hydroxypropyl < methyl < benzyl = propyl < isopropyl < phenyl < pentyl. This figure clearly illustrates the influence of the ligand structure on the retention of proteins in HIC. Other ligand types that can be used include silica-based ether-bonded alkyl phases, neopentylagarose, and phenylagarose.

4.2.2 Mobile Phase

Selectivity in HIC can be manipulated by changes in the nature of the eluting salt, salt concentration, pH, temperature, and the addition of mobile phase modifiers. Protein retention is strongly dependent on the type of salt employed. Salts defined as being kosmotropic or structure-making are used as they enhance hydrophobic interactions through a salting-out mechanism. This effect is formerly described in Eq. 8 in terms of the molal surface tension increment σ, the values of which are listed in Table 1 for a selection of commonly used salts in HIC. The salts with a higher σ-value will result in longer protein retention times. There have been a number of studies that have documented

Tab. 1 Molal surface tension increment for salts used in HIC[1].

Salt	*σ (×10³ dyn-g/cm-mol)*
Na_3PO_4	2.88
Na_2SO_4	2.74
$(NH_4)_2SO_4$	2.17
Mg_2SO_4	2.06
Na_2HPO_4	2.03
NaCl	1.64
KCl	1.50

the influence of different salts on protein retention in HIC. An example of the effect of salt on the retention of lysozyme in HIC is shown in Fig. 13. $(NH_4)_2SO_4$ is the most commonly used salt in HIC, while Na_2SO_4 and NaCl also find application. $(NH_4)_2SO_4$ has a high solubility and low UV absorbance and is readily available in high purity required for HPLC. Initial salt concentrations usually range from 1 to 3 M, and the starting concentration can also influence selectivity of a separation.

The pH of mobile phases used in HIC is typically between 5 and 7 and buffered

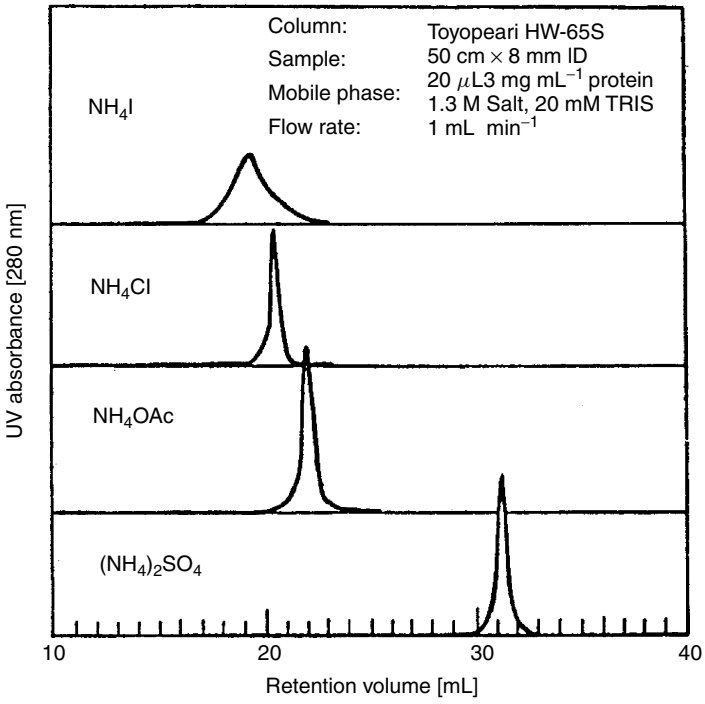

Fig. 13 The effect of salt on the elution of lysozyme in HIC. Column; Toyopearl HW-65S (Toyo Soda), 50 cm × 8 mm ID, 30-μm particle size, 100-nm pore size. Conditions; isocratic elution with 20 mM TRIS, pH 7, containing 1.3 M ammonium iodide, chloride, acetate, or sulfate, at a flow rate of 1 mL min^{-1} (Reprinted with permission from Rogetter, B.F. et al. (1990) in: Ladisch, M.R., Willison, R.C., Painton, C.C., Builder, S.E. (Eds.) *Protein Purification: From Molecular Mechanisms to Large Scale Processes*, American Chemical Society, Washington, DC, pp. 80–92).

with sodium or potassium phosphate. The influence of pH on protein retention is dependent on the particular protein as the manipulation of charges located in or near the hydrophobic binding domain will have a profound effect on the affinity of the protein for the sorbent material. Thus, changes in pH represent a useful parameter for modulating selectivity.

The gradient shape is an additional parameter that can be used to manipulate selectivity in HIC. An example of the influence of gradient time on the HIC separation of proteins is illustrated in Fig. 14. The LSS model can also be applied to the retention behavior of proteins in HIC and generally reveals a linear dependence of retention on salt concentration. The

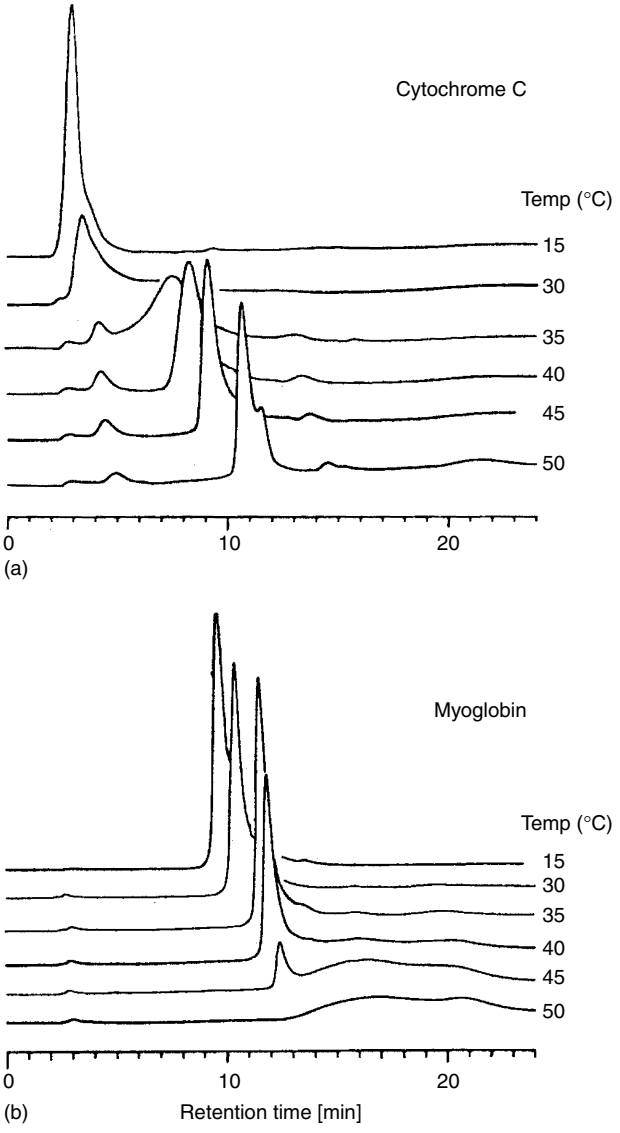
selection of elution conditions to maximize resolution between components therefore follows the same rationale as described for RPC in the previous section.

The addition of other solvent modifiers has also been shown to affect retention in HIC through changes in the surface tension of the mobile phase. These include detergents such as Triton X-100 and CHAPS, organic solvents such as 5 to 20% methanol, acetonitrile or even ethylene glycol and urea or guanidine hydrochloride at concentrations of 1 to 2 M. In all cases, it is possible for these additives to cause denaturation of the target proteins, so care is needed to minimize protein



conformational changes when introducing these additives to the mobile phase.

Temperature can also be used to manipulate selectivity in HIC through changes in protein conformation. Depending on the protein solute, chromatography in the range 15 to 50 °C can be used to sharpen the shapes of individual peaks and hence improve resolution as can be seen for myoglobin in Fig. 15(b). However, significant band broadening can also be observed as a result of slow conformational interconversions, which results in a decline in resolution as is evident in Fig. 15(a) for cytochrome *C*.

Overall, HIC is a powerful tool for the purification of proteins in a biologically active form. Moreover, protein structure and conformation play a crucial role in the chromatographic behavior of proteins and subtle changes in selectivity can be achieved through changes in the relative solubility and three-dimensional structure of the protein solute.

5
Ion-exchange Chromatography

High-performance ion-exchange chromatography (IEC) is now extensively used in the analysis of proteins, and also to a lesser extent for the analysis of peptides. The early stages of protein purification generally utilize solubility-based techniques to carry out the initial fractionation. Differences in size and shape of the proteins are then exploited through application of size exclusion or preparative electrophoretic techniques. Adsorptive techniques, including IEC and RPC are then introduced to allow rapid increases in the level of resolution, recovery, and product purity.

A significant advantage of IEC over the other adsorptive modes of chromatography is the nondenaturing effects of the solutions used to elute proteins from the ion-exchange sorbents. Thus, while gross conformational changes can be observed in RPC, these are not commonly found in IEC of proteins.

5.1
Basic Principles

Protein retention in ion-exchange chromatography arises from electrostatic interactions between the peptide or protein and the charged sorbent material and solutes are eluted by increases in the concentration of a displacer salt. As a consequence, the ''net charge'' concept is widely used to predict the retention characteristics of proteins with both anion and cation-exchange materials. According to this model, and as illustrated in Fig. 16, a protein will be retained on a cation-exchange column if the solvent pH is lower than the pI of the protein. Conversely, a protein will be retained on an anion-exchange column if the pH is above the pI of the protein. With mobile phases operating at a pH equal to the protein's pI, the surface of the protein is considered to be overall electrostatically neutral and under these conditions, the protein should not be retained on either cation or anion exchangers.

While this model can be used to predict the retention behavior of peptides in IEC, this classical model is recognized as a simplistic approach to describing protein retention. The amphoteric nature of proteins results in the existence of localized areas of electrostatic charge at different pHs, which can allow the protein to be retained even under conditions where the protein may be at its isoelectric point.

A number of more detailed models have been developed to describe protein retention in ion-exchange chromatography.

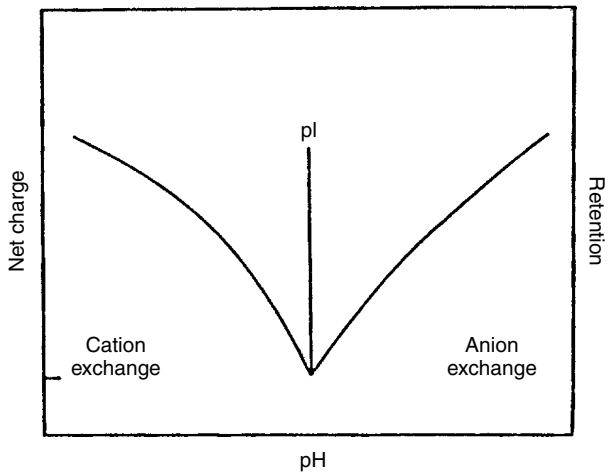


Fig. 16 The theoretical relationship between protein net charge and chromatographic retention in ion-exchange chromatography.

These include the stoichiometric displacement model and different approaches to solving the Poisson–Boltzmann equation for the interaction of charged surfaces. Each of these approaches attempts to provide a mechanistic description of the retention of proteins in IEC and provides a theoretical basis for the experimentally observed linear relationship between the solute retention and either (a) the reciprocal of the displacing salt concentration c, as follows

$$\log k' = \log K_O + Z_C \log(1/c) \qquad (10)$$

or (b) the corresponding ionic strength, I, according to

$$\log k' = \log K_O + B(1/\sqrt{I}) \qquad (11)$$

where K_0 is a constant, which incorporates a number of terms including a binding constant, the phase ratio of the packing material and various charge valency terms and can be determined by linear regression of plots of log k' versus log $(1/c)$ or plots of log k' versus $1/\sqrt{I}$. An example of the linear dependency of protein retention on log $(1/c)$ is shown in Fig. 17 for the isocratic and gradient elution of ovalbumin and carbonic anhydrase by strong anion-exchange chromatography. Z_C is the slope of these plots and can be related to the size of the electrostatic contact area established between the solute and the stationary phase. In addition, the LSS model can be used as the basis to optimize separations as described previously for RPC, through establishing the experimental conditions that maximize the separation of these plots for different components in a mixture. The variation in protein retention with changes in displacer salt concentration can be seen in Fig. 18 for the isocratic separation of myoglobin, carbonic anhydrase and ovalbumin using sodium chloride as the displacer salt.

Overall, it has now been established that the magnitude of electrostatic interactions between proteins and the charged sorbent material in IEC depends on the number and distribution of charged sites on the solute molecule that define the electrostatic contact area of the protein, the charge density of the sorbent, and the mobile phase composition. In summary,

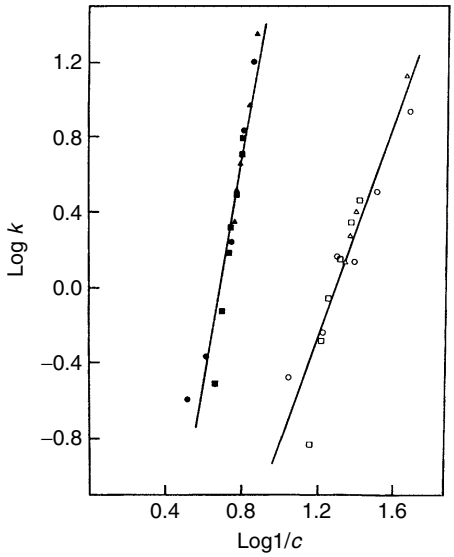

Fig. 17 Retention plots for the isocratic and gradient separation of ovalbumin (filled symbols) and carbonic anhydrase (open symbols) by strong anion-exchange chromatography. Column; Mono-Q HR 5/5, (Pharmacia, Uppsala, Sweden) Conditions; 0.02M piperazine at pH 9.6 with sodium bromide as the displacer. (Reprinted from Hodder, A.N., Aguilar, M-I., Hearn, M.T.W. (1989) The influence of different displacer salts on the retention properties of proteins separated by gradient anion-exchange chromatography, *J. Chromatogr.* **476**, 391–411, with kind permission from Elsevier Science – NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands).

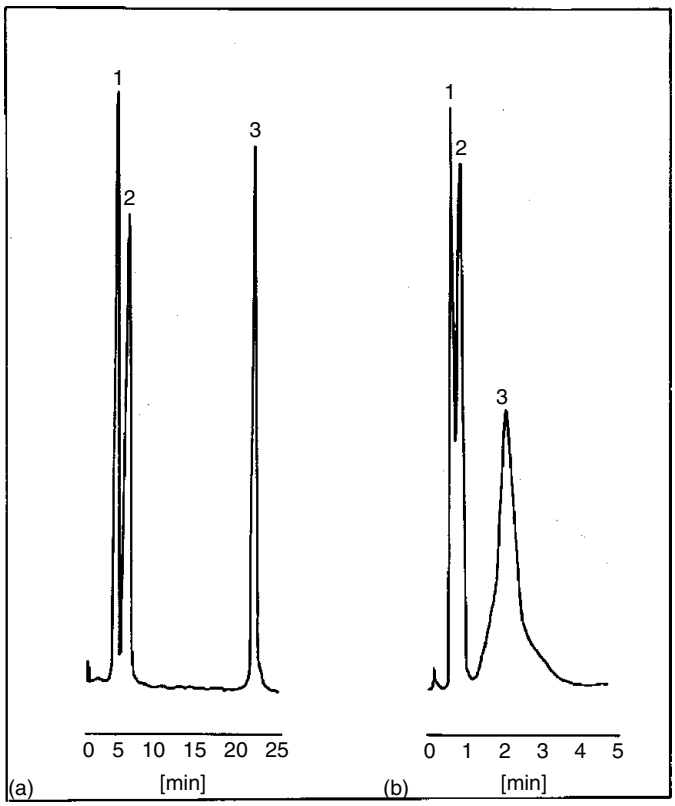

Tab. 2 Commonly encountered ligands for ion-exchange chromatography.

Ion exchanger	***Functional group***	
Strong cation exchanger (SCX)	Methylsulphonate	$-CH_2SO_3^-$
Weak cation exchanger (WCX)	Carboxymethyl	$-OCH_2COO^-$
Strong anion exchanger (SAX)	Methyl trimethyl ammonium	$-CH_2N^+ (CH_3)_3$
Weak anion exchanger (WAX)	Diethylaminoethyl	$-OCH_2H_2N^+ H(CH_2CH_3)_2$

the magnitude of the electrostatic interactions, and hence retention, in IEC is dependent on the following structural and chromatographic parameters:

1. the number and distribution of charged sites on the solute molecule that constitute the electrostatic contact area;
2. the charge density of the immobilized charged ligand;
3. the mobile phase composition.

It is these parameters that represent the factors that can be used to manipulate peptide and protein surface charge to allow optimization of selectivity in IEC.

5.2 Factors Influencing Retention in IEC

5.2.1 Stationary Phases

The support materials available for high-performance ion-exchange chromatography are generally silica-based or polymer-based materials. An ion-exchange material is selected on the basis of the desired particle and pore size, swelling characteristics at the operational pH range. However, the major factor is the capacity of the ion exchanger, which depends on the nature of the charged functional groups and the charge density as well as the pore size of the material and the charge distribution on the protein solute.

The two classes of ion exchangers are cation exchangers, which contain negatively charged functional groups, and anion exchangers, which contain positively charged functional groups. The most commonly encountered ligands are listed in Table 2. Strong cation exchangers normally contain sulphonic acid groups while strong anion exchangers contain quaternary ammonium functional groups. The charged ligands in weak cation exchangers generally contain carboxylic groups while weak anion exchangers are primary, secondary, or tertiary amines. The terms strong and weak refer to the degree of ionization with pH as strong ion exchangers are completely ionized over a much wider pH range than weak ion exchangers. The physical properties of some typical anion and cation exchangers used in protein chromatography are listed in Table 3.

5.2.2 Mobile Phases

The selectivity of proteins in IEC can be manipulated by variation in solution pH and ionic strength, which alters the electrostatic surface potential of the protein solutes and the charged ligand thereby influencing the strength of the electrostatic interactions. Changes in the nature of the displacer ion and the buffer species represent additional methods by which protein retention can be modified.

While NaCl is the most commonly used ionic displacer, a number of other monovalent and multivalent salts can be used. The ions may influence retention through specific interactions with the ion-exchange ligand, thereby changing their ionic properties. In addition, specific salts may alter the conformation of proteins, which in turn will influence their retention behavior. At fixed ionic strengths, anions can be ranked in terms of solute retention as follows:

$$F^- < CH_3COO^- < Cl^- < HPO_4^{2-} < SO_4^{2-}$$

Similarly, cations are ranked according to the series

$$K^+ < Na^+ < NH_4^+ < Ca^{2+} < Mg^{2+}$$

KCl, NaOAc, $MgCl_2$, $Mg_3(SO_4)_2$ have all been used for the analysis and purification of a wide range of proteins. The effect of different displacer salts on protein retention in weak anion-exchange chromatography is shown in Fig. 19, which illustrates the profound influence that the nature of the salt can exert on the electrostatic interactions between proteins and ion-exchange materials.

The selection of buffer depends on the pH range required to adsorb the protein to the stationary phase. While selection of a pH can be a straightforward task based on the known pI of the protein, for proteins of unknown pI or closely related proteins such as isoforms or recombinant muteins, a map of retention versus pH can assist in the selection of mobile phase pH. An example of the changes in selectivity, which can occur over a given pH range, is shown in Fig. 20 for the separation of a series of lysozymes by cation-exchange chromatography. Once the pH range is established, additional changes in selectivity can be obtained through changes in the nature of the buffer species. The most commonly employed buffer species include phosphate and tris buffers. A range of buffers, which are commonly used in IEC of proteins, is listed in Table 4.

Tab. 4 Buffers commonly used in IEC.

pH range	*Buffer*
Cation exchange	
1.5–2.5	Maleic acid
2.6–3.6	Citric acid
3.6–4.3	Lactic acid
4.8–5.2	Acetic acid
5.0–6.0	Malonic acid
6.7–7.6	Phosphate
7.6–8.2	HEPES
Anion exchange	
4.5–5.0	*N*-methyl piperazine
5.0–6.0	Piperazine
5.8–6.4	Bis-tris
7.3–7.7	Triethanolamine
7.6–8.0	Tris
8.5–9.0	1,3-diaminopropane
9.5–9.8	Piperazine

5.2.3 Operating Parameters

While isocratic elution can be used to separate proteins in IEC, gradient elution is generally employed to obtain high-resolution separations of proteins in IEC. Linear elution over 16 to 120 min is

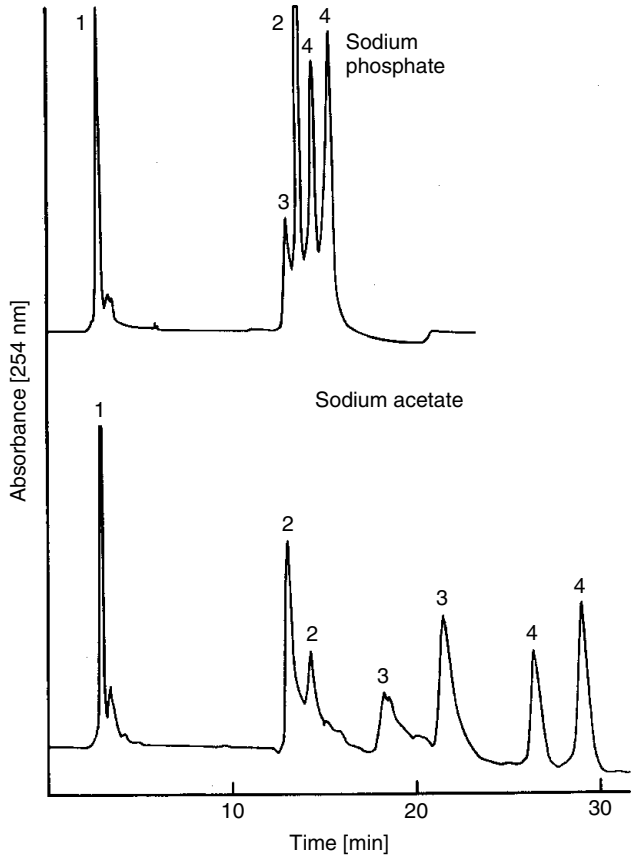

Fig. 19 The effect of different displacer salts on the retention of proteins separated by weak anion-exchange chromatography. generally applied between ionic strengths ranging from 0 to 0.5 M salt. Buffer concentrations usually range between 20 to 50 mM.

A number of additional materials can be added to the mobile phase to further enhance selectivity. For example, hydrophobic interactions may contribute to peptide and protein retention in IEC due to the nature of the stationary phase material. It has been reported that solutes cannot be eluted with some ion exchangers without

the addition of acetonitrile or methanol to the mobile phase. The percentage organic modifier is usually in the range of 10 to 40%. Higher levels of solvent can cause salt precipitation and may also affect protein conformation.

5.3 Peptide Separation in IEC

For peptide applications where incomplete separation is observed in RPC, ion-exchange chromatography represents

a very useful alternative separation mode. At neutral pH, basic peptides can be separated by cation-exchange chromatography and acidic peptides can be analyzed by anion-exchange chromatography. However, ion exchange of peptides is more commonly carried out at acidic pH, in the range 2.5 to 3.0, where most peptides are

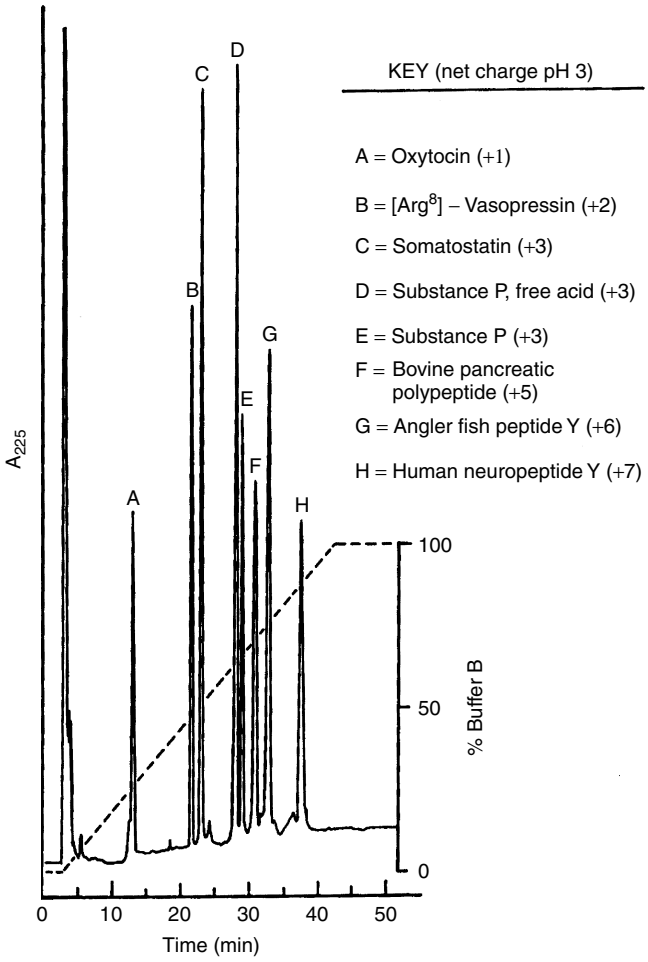

Fig. 21 Separation of a series of peptides by cation-exchange chromatography. Column; PolySULFOETHYL Aspartamide, 20 cm × 4.6 mm ID, 5 µm-particle size, 30-nm pore size (PolyLC, Columbia, MD). Conditions; linear gradient from 0 to 0.25 M potassium chloride in 5 mM potassium phosphate pH 3 and 25% acetonitrile at a flow rate of 0.7 mL min^{-1}. The peptides vary in net charge from $+1 \sim +7$ as indicated in the figure. (Reprinted from Alpert, A.J., Andrews, P.C. (1988) Cation-exchange chromatography of peptides on poly(2-sulfoethyl aspartamide)-silica, *J. Chromatogr.* **443**, 85–96, with kind permission from Elsevier Science – NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands).

positively charged and hence cation exchange is applicable. At this pH range, the negative charges associated with aspartate and glutamate residues and the C-terminus are neutralized, while arginine, lysine, histidine residues and the N-terminus are positively charged.

Commonly used solvents for peptide IEC are usually based on phosphate buffers with NaCl or KCl as the displacer ion. For peptides up to approximately 50 residues in length with no significant secondary structure, retention is governed by the number of positive charges as illustrated in Fig. 21, which shows the separation of eight peptides ranging in overall net charge of $+1 \sim +7$. Thus, peptides differing by a single charge are generally well resolved. However, peptides with the same charge but different amino acid composition can also be separated because of differences in overall charge density. In addition, hydrophobic interactions may also contribute to the retention of peptides with ion-exchange resins. In these cases, organic solvent can be added to the mobile phases to further modulate selectivity. 10 to 40% v/v of either methanol or acetonitrile can be used and an example of the selectivity changes with the addition of acetonitrile is shown in Fig. 22 for a series

of peptides separated by strong cation-exchange chromatography.

In summary, high-performance ion-exchange chromatography continues to be an important technique for the analysis and purification of proteins under mild nondenaturing conditions and also provides a very useful selectivity alternative for the analysis of peptide samples.

6 Size Exclusion Chromatography

Size exclusion chromatography (SEC) is frequently used as the first step in the isolation of proteins from complex mixtures where separation is carried out according to molecular size and shape. SEC can also be used for desalting samples through buffer exchange and has also found application in the analysis of peptides. SEC has also been established as a physicochemical tool for estimating molecular size and shape of proteins and has provided insight into protein folding mechanisms by monitoring changes in protein size as a function of changes in the concentration of chemical denaturants.

6.1 Basic Principles

Separation in SEC is based on differences in molecular size in solution. Porous stationary phases with defined pore diameters and elution conditions are used that minimize interaction between the solute molecules and the stationary phase material. The larger the molecule, the smaller the amount of accessible pore volume. Molecules that are larger than the largest pore diameter cannot penetrate into the stationary phase pores and pass through the column with the fastest retention time. These molecules are eluted with V_o, while the smallest molecule is eluted in V_t, the total volume of the column. V_t is the sum of the void volume and the interstitial volume V_i, *that is*,

$$V_t = V_o + V_i \tag{12}$$

Solute elution volume in SEC is denoted by V_e which should be between V_o and V_t and can be expressed as follows

$$V_e = V_o + K_d V_i \tag{13}$$

where K_d is the distribution coefficient, which defines the fraction of internal volume which is accessible to the protein solute.

6.2 Experimental Conditions

The packing materials available for high-performance SEC are generally silica-based or polymeric. The pore diameter of SEC supports determines the exclusion limits of the material. Columns are characterized in terms of the molecular weight range, which can be adequately separated and is dependent on the pore diameter. Generally, the pore diameter ranges between 100 and 500 Å. The pore volume is also an important property of an SEC material, which must be sufficiently large to provide a high peak capacity, that is, the ability to separate seven peaks with a resolution of one. Column efficiency in high-performance SEC supports is particularly important as solutes are eluted isocratically and therefore do not exhibit band sharpening, which occurs with gradient elution. SEC supports generally have particle diameters between 5 and 10 μm.

The hydrodynamic shape and volume rather than molecular weight *per se* is the

physical property of proteins that causes separation in SEC. In order to achieve accurate estimations of molecular weight, a column must be calibrated with molecules that have the same overall shape. Under ideal conditions, K_d will be proportional to the logarithm of the molecular weight of the protein as illustrated by a typical calibration curve shown in Fig. 23 for the protein separation shown in Fig. 24. While the majority of applications of SEC have involved the analysis and purification of proteins, SEC has also recently been used in the analysis of peptides. An example of the high level of resolution that can be achieved for peptides is shown in Fig. 25, which demonstrates excellent separation in the MW range of 75 to −12 500 Da.

Mobile phase selection is important in SEC to minimize nonspecific interactions between the support and the solutes and also to avoid mobile phase induced changes in solute molecular shape. Both ionic and hydrophobic interactions can also contribute to the elution volume of proteins in SEC as most packings are weakly acidic (due to residual negative charges) and/or mildly hydrophobic. Ionic interactions can be minimized by increasing the ionic strength of the mobile phase through the addition of up to 0.5 M NaCl. However, increasing ionic strength also results in the enhancement of hydrophobic interactions. Thus, a balance is necessary to minimize both the undesired interactions. A common mobile phase composition that is employed for SEC of proteins is phosphate buffer at pH 7 with ionic strength of 0.05 to 0.1. Thus, by optimizing pH and ionic strength, secondary interactions can be almost excluded. However, ionic or hydrophobic interactions can also be used to manipulate selectivity of protein separations. The example shown in

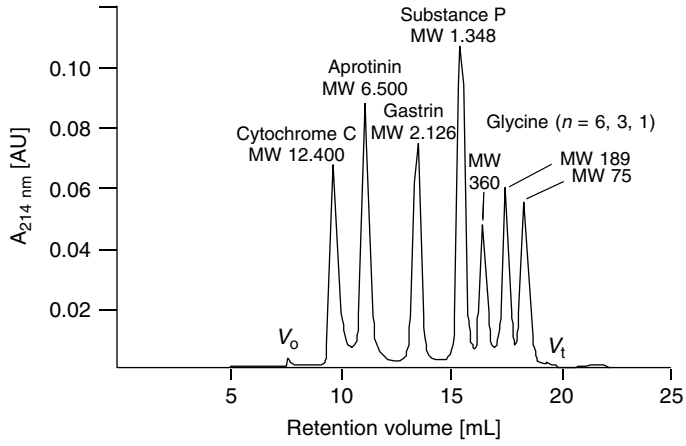

Fig. 23 A typical calibration curve for the separation of proteins by size exclusion chromatography. column; SynChropak GPC300, 30 cm × 7.8 mm ID, 5-µm particle size, 30-nm pore size (SynChrom, Linden, IN). 7
Capillary Liquid Chromatography

7.1
General Considerations

The transfer of analytical HPLC methods from conventional-size columns with typical 3.0- to 4.6-mm ID to capillary size dimensions of 0.1- to 0.5-mm ID has been a significant advance in recent years bringing several advantages such as reduction in the consumption and disposal of solvents, working with limited sample amounts and efficient interfacing with electrospray ionization MS. In principle, the various mechanisms utilized in conventional LC separations can be effectively implemented in packed capillary formats. However, most separations utilizing capillary LC are now performed using the reversed phase mode of separations.

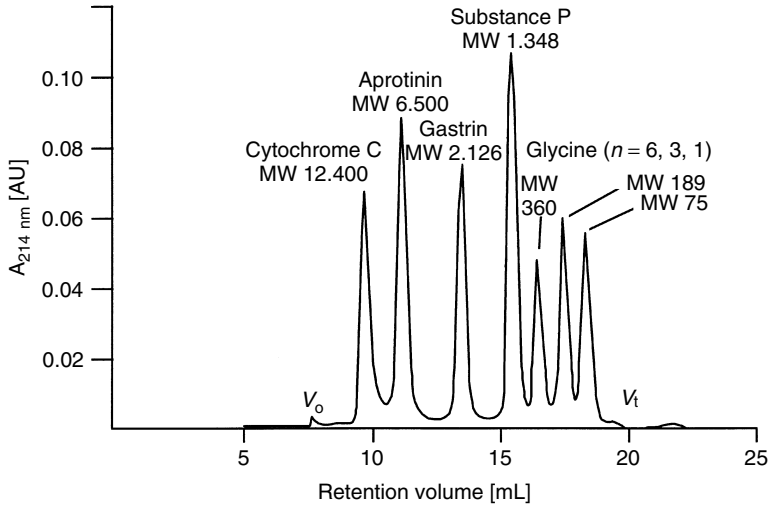

Fig. 25 The separation of peptides by size exclusion chromatography. Column; Superdex Peptide HR 10/30 (Pharmacia, Uppsala, Sweden). Conditions; 0.25 M NaCl in 0.02M phosphate buffer pH 7.2, flow rate 0.25 mL min^{-1}. (High-performance size exclusion columns Data file No 18-1106-06, 1994, courtesy of Amersham Pharmacia Biotech).

This is primarily because RPC is highly compatible with MS detection using ESI and requires only low flow rates to achieve both high separation efficiency and high detection sensitivity. Other modes of LC separation commonly utilized in peptide/protein separations include IEC, SEC, HIC, and affinity chromatography. Many of these modes of chromatography are utilized in sample clean up, preconcentrations, or fractionation before final analyses.

Compared to the various modes of LC, RPC generates the highest separation efficiencies because of the fast mass transfer of analyte between the stationary and mobile phases. Simultaneously, RPC facilitates high detection sensitivity through its compatibility with MS. Figure 27 shows the LC-MS analysis of an Arg-C digest of plasminogen activator separated on a C18 column, with the total ion current in the upper trace and the elution profile detected at 214 nm in the lower trace. The availability of on-line mass spectrometry thus significantly facilitates the identification of the peptide fragments. Other important applications involve the identification of posttranslational modifications of peptides and proteins, assignment of disulfide bonds and the identification of peptides bound to major histocompatibility complex molecules.

The separation efficiency of RPC is highly dependent on the maximum operating pressure that is determined by the column length, internal diameter, and particle size that can be used in a given separation. The primary limitation for using high-pressure capillary LC in routine peptide/protein analysis has been the need for off-line sample introduction. On-line, high-pressure-resistant switching valves with pressure limits of at least 20 000 psi, are under development. The application of a 20 000-psi capillary RPC

system for routine proteomic analyses is to be expected. High-efficiency capillary LC is now being performed at 10 000 psi using ~85-cm-long capillaries that have inner diameters from 15 µm to 150 µm packed with 3-µm porous particles. At such pressures, special switching valves with positive-feedback sealing are required for sample introduction, and separations generating peak capacities of $\sim 10^3$ for global cellular proteolytic polypeptide mixtures have been demonstrated.

For capillary separations of intact proteins, it is estimated that peak capacities of $\sim 10^2$ can be achieved, but the resolving power is not sufficient for separating complex proteomic protein mixtures (e.g. containing ~1000 proteins), and multidimensional separations are typically required. Few literature reports describe RPC applications for resolving protein complexes, probably because of the relatively strong interactions between the analyte and the stationary phase. As discussed in Sect. 3, proteins tend to denature under reversed-phase conditions (low pH and high organic solvent concentrations) making their quantitative elution rather difficult and measuring the molecular mass of a whole protein is not sufficient for

its unambiguous identification. For this approach to be successful, it is necessary to digest all of the proteins in a sample and to perform the separation at the peptide level.

The ability to effectively load significant amounts (either volume or mass) of sample onto the capillary column to improve detection capabilities for low-abundance species is particularly important to proteomic applications. In isocratic capillary LC separations, limitations for large volume sample loading result from degradation of separation efficiency. Under composition gradient conditions, however, introduction of a relatively large sample volume can be conducted without significant loss of separation efficiency. This is because the sample can be ''focused'' on the head of the column inlet in the weakly solvating mobile phase used for sample introduction. However, as the sample loading time is proportional to sample volume, a long-extended sample injection time is required for this case. For example, introducing a 10 µL sample with optimum LC linear velocities (e.g., ~0.1 cm min^{-1}) onto a 150-µm ID capillary column requires ~20 min. Use of high mobile phase linear velocities can shorten the sample loading time. However, the use of long capillaries packed with small particles limits the maximum mobile phase flow rate that current LC pumps can supply because of pressure limitations. In practice, relatively small volume injections having high sample concentrations can be used to reduce analysis time. For example, a *Deinococcus radiodurans* tryptic digest with concentrations (protein content) up to ~50 µg $µL^{-1}$ has been successfully loaded onto a 150-µm ID packed capillary column. However, introducing more concentrated samples is problematic because their viscosities are too large to easily allow manipulation with a syringe.

The achievable sample mass loading capacity depends on the specific column dimension, the chromatographic packing material properties, and the analyte properties. A capacity of 20 to 200 µg g^{-1} of packing material can be estimated for RPC from these previous studies, although different sample capacities have been reported. For long packed capillaries having ~150-µm ID, the sample loading capacity can be estimated to be 0.15 to 1.5µg for an individual analyte. In global cellular proteolytic digest samples (cellular proteome), hundreds of thousands of polypeptides are potentially present, having large differences in both quantity and physicochemical properties. Using an online guard column or SPE column can be used to resolve this problem.

7.2 Capillary RPC of Proteolytic Peptides for Proteomic Analysis

Capillary RPC separations of global protein tryptic digests for proteomic studies are attracting increased attention. Such techniques are commonly carried out using acetonitrile as the organic solvent in the mobile phase(s) to achieve high-efficiency separations of complex mixtures that contain a variety of properties of proteolytic peptides. Perfluorinated carboxylic acids (e.g. trifluoroacetic or heptafluorobutyric acid) can be used as an acidic modifier in the mobile phase with ESI-MS detection conditions. Octadecyl-bonded silica particles (i.e. C18 particles) are typically used as the stationary phase. The high-quality silica matrix used for the bonding reactions is attractive for eluting strongly basic peptides. Porous particles are useful for obtaining large sample capacities. At an operating pressure of 10 000 psi (the present practical

limit for reproducible sample introductions using switching valves), ~85-cm columns packed with 3-μm particles can achieve high-efficiency separations. The use of very small particle sizes at this pressure limits the total separation efficiency. Current high-efficiency capillary LC can be performed with column inner diameters from 15 to 150 μm, corresponding to flow rates from 20 nL min^{-1} to 1.5 μL min^{-1} at their optimal linear velocities to obtain peak capacities of $\sim 10^3$. This provides great flexibility for column selection to achieve the desired MS sensitivity for a specific sample amount.

In order to improve the throughput of gradient capillary RPC, high-efficiency multiple-capillary LC separations have been implemented with a single LC pumping system consisting of several dual-capillary column devices that operate at constant pressure. These dual-capillary column devices are serially connected to two high-pressure mobile phase lines, fed using independent LC pumps (mobile phase A and mobile phase B). Each dual-capillary column device is composed of a mobile phase mixer (2.8 mL), a switching valve for mobile phase gradient, a split line (30-μm ID fused silica), a switching valve sample injector, two capillary separation columns, and a column switch valve. While constant pressure LC operation offers limited flexibility for manipulating the mobile phase gradient to optimize separation selectivity, reliably obtaining high separation efficiencies is more important for separations of highly complex samples such as global cellular protein digestions. The only limitation to the number of such capillary column devices that can be connected in a single system results from the flow rate of the high-pressure LC pumps. For example, if each dual-capillary column device operates at a mobile phase flow rate of ~20 μL min^{-1} (including splitting, typically used for our capillary LC experiments), up to ten dual-capillary column devices can be connected using pumps that supply a stable flow rate of ~0.2 mL min^{-1} at the desired pressure. The separation efficiency and reproducibility of the multiple-capillary LC separations have been experimentally evaluated. Comparing the separation results of a yeast tryptic digest for the dual-capillary column device with the results obtained using single capillary LC shows that the same separation efficiency was reproducibly obtained with both capillaries for this extremely complex sample. The average errors for elution time and peak height are 4 and 8%, respectively, for recognizable peaks with elution times of <50 min, and were only 1.8 and 5%, respectively, for recognizable peaks eluting between 50 and 170 min. Currently, the role of capillary RPC in the analysis of proteome-wide proteolytic peptides has been limited to resolving these peptides. The information from peptide elution properties on RPC columns has not yet been fully utilized for helping peptide identification. Understanding peptide elution behavior relevant to their structures will greatly improve the accuracy and confidence in MS identification of separated peptides.

Capillary RPC of proteins is limited to medium efficiencies (peak capacities of $\sim 10^2$), and its application in proteomic analysis is, at the present time, generally applied to only relatively simple protein systems. However, detailed analysis of intact proteins for yeast large ribosomal subunits has been studied by the capillary RPC. Capillary RPC of membrane proteins and construction of two-dimensional separations for complex protein mixtures are worthy of future investigation.

7.3 Capillary Ion-exchange Chromatography

IEC is primarily used for sample fractionation of either proteomic intact proteins or their proteolytic peptides, and is usually practiced using microcolumns or even conventional columns. However, because of sensitivity requirements for proteomic analysis, the use of capillary IEC is appealing. Capillary IEC can generate peak capacities of 200 to 400 for both cellular proteins and their proteolytic polypeptides. The sample capacity has been found to be significantly smaller than for capillary RPC using the same dimensions of packed capillary columns. For example, <100 µg of an yeast lysate tryptic digest can be loaded on an 85 cm × 150 µm ID capillary packed with 3-µm SCX particles (300 Å pores), while ~500 µg of the same sample can be loaded on the same dimension capillary packed with 3-µm C18 particles (300 Å pores). Desalting of samples can improve the loading capacity to some extent. These properties are important in the selection of capillary column dimensions for two-dimensional separations, particularly considering issues related to detection sensitivity (i.e. with MS). Additionally, IEC elution properties of proteins and peptides potentially provide valuable information for assisting protein identification.

7.4 Other LC Methods

Other LC separation mechanisms such as SEC and affinity chromatography have also been used for peptide/protein studies. Currently, these separations are primarily used for proteomic sample processing, such as sample purification, isolation of interested proteins, and in some situations, sample fractionation. Most of these applications are performed using larger column LC, and their implementation with capillary columns promises to improve the overall sensitivity.

7.5 Multidimensional Capillary Separations for Proteins

Because of the complexity of proteomic samples, two or even multidimensional separations appear attractive for achieving high-resolution separations. Although comprehensive two-dimensional LC separations have been developed, the fast separation in the second dimension (currently) is generally far from optimal for data-dependent MS/MS peptide identification (e.g. using ion trap MS). Additionally, the interface between the first and the second dimension separation also effectively degrades the detection of low-abundance species. The two-dimensional separations that have been used for proteomic analyses to date achieve their separation efficiencies (combined peak capacities of $\sim 10^3$) primarily from the second dimension separation, while the first dimension separation is only used for a limited number of sample fractionations (typically the fraction number is <20). The separation of total human plasma proteins digested with trypsin with high-efficiency capillary SCX/RPC is demonstrated in Fig. 28. Although used in this way, the first dimension separation efficiency is also important because it determines the number of overlapping (or repeated) components in neighboring fractions. Both CE and capillary LC can also be used as the first separation dimension for sample fractionation; however, the separation sample capacity for the first dimension and the fluid compatibility with MS for the second dimension have to be

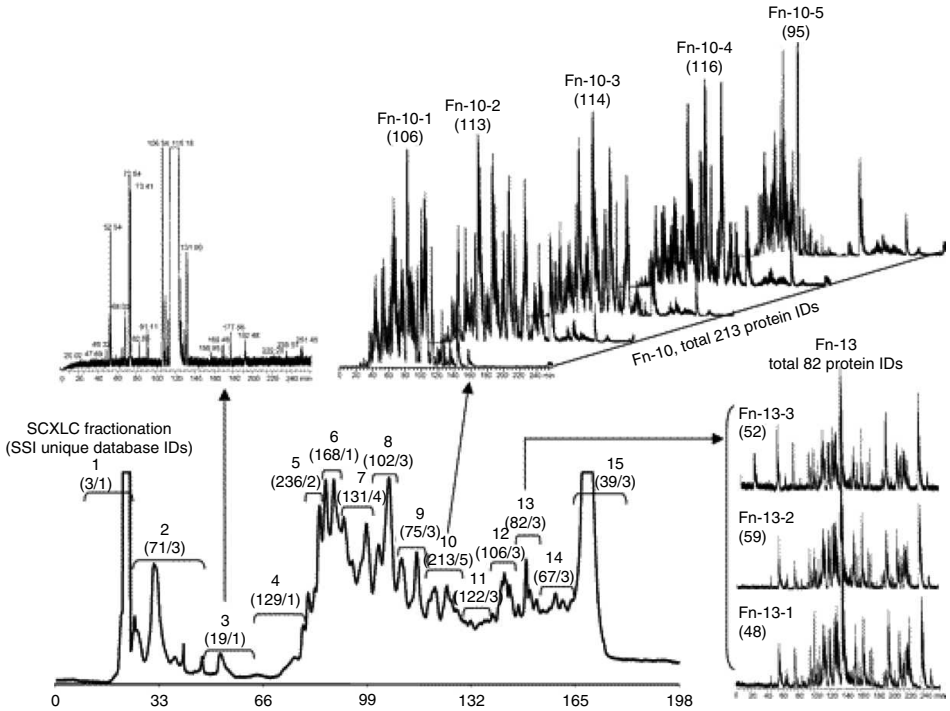

Fig. 28 High-efficiency 2D capillary SCX/RPC separation of total human plasma proteins digested with trypsin. The total plasma tryptic digests were first separated in an 80 cm × 320 µm ID fused-silica capillary packed with polysulfoethyl aspartamide-bonded silica particles (3-µm diameter, 300-Å pore size). A linear gradient of 4 mM phosphate, pH 2.5 to 0.4 M phosphate buffer in 200 min was used to separate the tryptic peptides. The peptides were separated into 15 fractions followed by RPC separation using an 85 cm × 30 µm ID capillary (packed with 3-µm C18 particles, 300-Å pore size). The number of proteins identified is given in parentheses. (Reprinted with permission from Shen, Y. et al. (2004) Ultra-high-efficiency strong cation exchange LC/RPLC/MS/MS for. . ., *Anal. Chem.* **76**, 1134–44).

considered when constructing such two-dimensional separations.

A combination of size exclusion with adsorptive chromatography, the so-called restricted access chromatography, has been implemented to separate protein mixtures. In this case, only proteins and peptides below a certain size have access to the inner pore surface of the stationary phase and are thus retained while the larger proteins encounter only the hydrophilic, nonadsorptive outer surface and are found in the flow-through. Restricted access materials have found widespread use in the analysis of drug metabolites and other low-molecular weight compounds but have only recently been rediscovered for peptide/protein studies. In an example of applying restricted access chromatography to the analysis of hemofiltrate, a biofluid that is comparable to urine, it was shown that the sample preparation step could be performed in line with a two-dimensional chromatographic separation. This allowed a peak capacity of about 5000 to be reached, a number that is comparable to the number of spots obtained on a highly optimized 2DE gel for

proteins. Such high-resolution, multidimensional systems promise to provide the methodological means for biomarker discovery in combination with modern mass spectrometers and data analysis software.

Yates and coworkers have introduced a serial two-dimensional LC for proteomic analysis. In this approach, a biphasic microcolumn in which a single capillary with 100-µm ID is first packed with 5-µm C18 for 8 cm and then packed with 5-µm SCX for 4 cm, which is similar to those used in serial column chromatography. The two-dimensional separations are achieved by alternatively eluting with salt step and a 60-min linear aqueous acetonitrile gradients through the whole biphasic column. The system is used for direct analysis of large protein complexes, and 95 unique proteins have been identified for the loaded 120-µ g mixture in ~24 h of a single run (12 cycles). After optimization of this multidimensional protein identification technology (MudPIT), it was applied to proteome-wide protein identification. Optimizations included fractionation of a yeast derived proteome sample into three fractions (i.e. soluble, lightly washed, and heavily washed fractions) prior to the tryptic digestion, extension of C18 packed column length to 10 cm, varying mobile phase composition by adding 0.02% heptafluorobutyric acid (HFBA), using shallow gradient, and utilizing 15 fractionation cycles. In ~84 h required for three runs of the three fractions, a combined 5540 peptides were assigned, leading to identification of 1480 proteins. In ~28 h of a single run, ~630 soluble proteins from 1665 assigned peptides were achieved for the soluble protein fraction. By analyzing the data set against the database, 72 out of 231 possible peripheral membrane proteins were detected and identified. The addition of HFBA to the mobile phase has significantly improved the sensitivity and separation resolution in the biphasic column. The separation efficiency of the MudPIT system was evaluated, and a peak capacity of 216 was achieved for the 5-µm C18 packed 10-cm capillary. Combined with 15 cycles (i.e. first stage fractions), a total peak capacity of 3240 was estimated.

7.6 Other Approaches

While off-line capillary isoelectric focusing (CIEF)/capillary RPC separations have been investigated for complex proteomic sample analysis, the use of either on-line CIEF/capillary RPC, capillary isotachophoresis (CITP)/capillary RPC, or capillary LC/capillary zone electrophoresis (CZE) for proteomic analysis has not yet been reported. However, their use is expected because of the relatively large sample capacity and separation efficiency of the first dimension and high separation efficiency supplied by the second dimension. Utilization of these approaches can potentially provide information that makes peptide and protein identification simpler and more accurate.

8 LC-MS for Peptide/Protein Analysis

One of the most significant recent advances in bioanalytical technology is the advent of mass spectrometry for the analysis and measurement of peptide and protein molecular mass. In particular, the development of on-line electrospray mass spectrometry following RPC (LC-ES-MS) has provided a powerful detection system for the rapid analysis of peptide and proteins. The identification of proteins, peptide fragments and various modifications

is essential for understanding biological processes and the function of proteins for normal healthy and at various disease states. The resulting insights lead to the development of therapies for intervention, and ultimately, the cure of disease. The information and knowledge derived from this type of study are extremely valuable for activities involved with target identification activities during drug discovery.

As described in previous sections, chromatographic analysis of peptide and protein is conventionally detected and quantified by the ultraviolet and/or fluorescence detection. However, quantitative methods combining separation techniques with UV or fluorescence detection are of limited applicability when analyzing highly complex biomolecule mixtures. Such samples require high-resolution baseline separations or exceedingly high concentrations of analytes to overcome the impact of the matrix, because of unselective UV/fluorescence detection. Therefore, effective and sensitive peptide/protein detection and quantification from biological samples demands highly selective, robust, and accurate LC-MS methods.

8.1 General Considerations

LC-MS is a versatile combination of a commonly used chromatographic technology and mass spectrometry, a powerful identification tool not only for proteins but for all classes of organic molecules. The coupling of LC with MS has had an enormous impact on small molecule and protein profiling, and has proven to be an important alternative method to two-dimensional gel electrophoresis. In the vast majority of LC–MS methods, the chromatographic conditions employed have significant influence on the operation of the mass spectrometer. This means that the chromatographic conditions will invariably have a significant, molecule-dependent effect on the mass spectrometry conditions required to obtain informational analytical results. Since there are a substantial number of parameters that may influence the final results that are obtained, formal experimental design procedures are increasingly being utilized to determine the experimental conditions that give optimum analytical performance, adequate accuracy and precision at appropriate levels. There are many examples in the literature of methodology that allows this to be developed and achieved without the need to use complex experimental design simply by varying individual factors that are thought to affect the experimental outcome. Examples include the conditions required to give complete chromatographic resolution of the analytes present, the minimum analysis time for a complex mixture or the most intense detector signal from some or all of the analytes. As an analytical method becomes more complex, the number of factors is likely to increase and the likelihood is that the simple approach to experimental design described above will not be successful. In particular, the possibility of interaction between factors that will have an effect on the experimental outcome must be considered and factorial design allows such interactions to be probed. Factors may be classified as ''quantitative'' when they take particular values, for example, concentration or temperature, or ''qualitative'' when their presence or absence is of interest.

For an LC–MS experiment, the ''factors'' could include the composition of the mobile phase employed, its pH and flow rate, the nature and concentration of any mobile-phase additive, for example, buffer

or ion-pair reagent, the makeup of the solution in which the sample is injected, the ionization technique, spray voltage for electrospray, nebulizer temperature for APCI, nebulizing gas pressure, mass spectrometer source temperature, cone voltage in the mass spectrometer source, and the nature and pressure of gas in the collision cell if MS–MS is employed. For quantification, the assessment of results is likely to be on the basis of the selectivity and sensitivity of the analysis, that is, the chromatographic separation and the maximum production of molecular species or product ions if MS–MS is employed. Among the various ionization methods developed for coupling LC to MS, including thermospray, continuous-flow fast atom bombardment, and particle beam techniques, electrospray ionization (ESI) is the most widely used interface technique.

8.2 Capillary RPC-MS

Capillary RPC-MS currently plays a dominant role in proteomic analyses involving peptide mixtures due to its robustness for a variety of peptide properties (highly acidic/basic and hydrophilic/hydrophobic). Following enzymatic digestion of the global whole-proteome proteins, the resultant extremely complex peptide mixtures can be directly analyzed using capillary RPC-MS or MS/MS. Sample fractionation prior to RPC has also been applied in some situations. Peptide identification can be conducted using either accurately measured masses (measured with sufficient accuracy to discriminate the identified peptides from others predicted for a proteome or genome) or, more conventionally, peptide fragments produced by MS/MS. The latter approach can be carried out using relatively simple MS such as ion trap MS, while both approaches can be performed using high-quality MS (such as Fourier transform ion cyclotron resonance (FTICR) MS) with improved identification confidence, sensitivity, and dynamic range. Recent results with smaller ID capillaries have shown that comparable results are achievable with much smaller sample sizes, for example, nanoproteomics with sample size of ~10 ng, equivalent to 100 eukaryotic cells. Relatively low separation efficiencies limit the use of single-dimensional capillary RPC-MS for intact protein analysis to relatively simple proteomic systems. This type of application has been successfully demonstrated by the capillary RPC-FTICR characterization of intact proteins from the large subunit of the yeast ribosome. For the capillary RPC separations, C-5 bonded silica particles (5 μm, 300 Å pores) are used as the stationary phase in a 120 cm × 150 μm ID fused-silica capillary (currently, desirable 3-μm porous particles are not commercially available) and acidic acetonitrile aqueous solutions (0.1% TFA as the acid modifier) are used in the mobile phases. For FTICR measurements, an internal calibrant delivered from a dual ESI source was used to achieve high mass measurement accuracy (but which are not as high as achievable for lower M_r peptides). The relatively high resolution achieved by capillary RPC permitted differentiation of protein isoforms having high structural similarity and proteins from their modified forms, thus facilitating unequivocal protein assignments. By providing information on intact proteins and their modifications, the capability of identifying intact proteins holds promise as a complement to the mass spectrometric approach based on protein digestion.

8.3 LC/MS for Protein Analysis

LC-MS has found widespread use in the analysis of peptides from natural sources or generated by proteolytic digestion of larger proteins. LC-MS has also been applied to large-scale global protein characterization and identification. While analyzing biofluids directly without prior digestion is a definitive option in biomarker discovery, prior digestion gives access to the higher molecular weight proteins; however, the analysis of the digested peptide fragments from larger protein mixtures is much more complex. A dynamic range of 4 orders of magnitude could be reached in the expression level of the proteins present. However, it might be that the order of 1000 proteins in a biofluid is still an underestimate, especially if one includes possible splicing variants and posttranslational modifications. This indicates that analysis of such complex mixtures will likely remain a challenge for some time to come no matter which analytical approach is taken. Application of LC-MS to biomarker discovery is not yet very widespread partly because the method generates large and highly complex data sets that require powerful algorithms and software tools to handle and analyze them. LC-MS generates information about the components in a sample both in terms of their physicochemical properties and their molecular mass. Insights given by chromatography such as hydrophobicity or charge of the analytes may provide additional information that can help in sample comparisons. This additional information is, however, presently not systematically used. Presently, LC-MS is more suitable for initial discovery efforts than for larger clinical validation studies. However, these challenges are being tackled so that LC-MS will likely find more use in the future.

The use of HPLC on-line or off-line is an essential feature for global protein analysis to integrate the removal of buffers and salts (purification) and the separation of analytes (preconcentration) with mass spectrometry. With on-line LC-MS approaches, low flow rates ($<100\ \mu L\ min^{-1}$) have been demonstrated to provide maximum sensitivity with ESI techniques for the analysis of proteins. In this type of analysis, a precolumn split of the mobile phase ($\sim 200\ \mu L\ min^{-1}$) was used to obtain a flow rate of $0.2 \pm 0.5\ \mu L\ min^{-1}$. This microcolumn HPLC method minimizes the column elution volume and maximizes the concentration of peptide that enters the ESI interface of the mass spectrometer. Other examples of low flow approaches include peak parking techniques, where the solvent flow and gradient are stopped and the sample continues to flow into the mass spectrometer. This procedure provides longer sampling times and an improved signal-to-noise ratio because the signal can be averaged for a greater length of time. On-line LC-MS approaches for peptide mapping are also used with ESI-time of flight (TOF) mass spectrometers. A nonporous silica support has also shortened the separation of peptide mixtures in less than 35 s. The resulting chromatographic peak widths are less than 1 s wide. The unique nature of the TOF mass spectrometry allows for the complete analysis of these narrow peaks. Off-line approaches also feature sample clean-up, preconcentration, and the batch elution of peptides. This offline feature is commonly used with MALDI-TOF techniques for the simultaneous analysis of peptide mixtures. Because these methods are decoupled from the actual analysis, highly

automated procedures can be used to prepare and manipulate samples.

9 Future Prospects

The number of applications of HPLC in peptide and protein purification continue to expand at an extremely rapid rate. Solid-phase peptide synthesis and recombinant DNA techniques have allowed the production of large quantities of peptides and proteins, which need to be highly purified. The design of multidimensional purification schemes to achieve high levels of product purity highlight the power of HPLC techniques in the production of peptide and proteins-based therapeutics.

Following purification, mass spectrometry can be used to confirm the structural identity of synthetic peptides, while recombinant proteins require further structural analysis by high-resolution analytical fingerprinting to confirm the amino acid sequence. RPC will therefore continue to be the central method for the characterization and quality control analysis of synthetic peptides and recombinant proteins. Moreover, the coupling of mass spectrometry to allow on-line identification of samples will become routine and continue to expand the analytical power of HPLC. Other coupled techniques such as LC-CE (capillary electrophoresis) and LC-biosensor will also allow more rapid on-line analysis of sample purity and bioactivity.

Other areas of separation technology in which significant advances are anticipated to emerge are in the areas of miniaturization and high-speed analysis to allow the efficient purification of femtomolar to attomolar levels of material. These techniques will have important impact in the discovery of new bioactive peptides and novel proteins as potential candidates for new therapeutics. However, in the postgenomic era, the overwhelming application of HPLC will be in the continuing development of new approaches to proteomic mapping.

Finally, there has been a strong synergy between the biotechnology industry and the field of biomacromolecular HPLC as several significant recent advances in separation technology have been driven by the stringent and continually evolving regulatory requirements of the biotechnology industry. HPLC will therefore continue to be at the heart of the analytical techniques with which scientists in both academia and the pharmaceutical industry must arm themselves to be able to fully characterize the identity, purity and potency of peptides and proteins.

Keywords

DNA Vaccine
Vaccine formulation in which eukaryotic expression vectors coding for the antigens of interest are given to the vaccines.

Inactivated Vaccine
Vaccine formulation prepared using killed organisms.

Live Vaccine
Vaccine formulation prepared using a live attenuated organism, which is not able to cause disease (i.e. nonvirulent organism).

Subunit Vaccine
Vaccine formulation prepared using purified subcellular components from pathogenic organisms.

Vaccine
Preparation administered to humans or animals, which is able to stimulate a protective immune response against a pathogenic organism.

Vaccination
Administration of a vaccine preparation to humans or animals.

Whole-cell vaccine
Vaccine formulation prepared using an intact organism (e.g. bacteria, virus).

Immunization, also called *vaccination*, is the most cost-effective intervention to prevent infectious diseases. This is achieved by stimulating the production of pathogen-specific antibodies and/or cellular immune responses. Vaccines have been mainly used for the prophylaxis of infections, that is, they are administered to a large number of healthy individuals to confer protection against disease. However, the development of therapeutic vaccines against infectious and noninfectious diseases is gaining interest. Classic antibacterial vaccines, which will be the main subject of this article, have played a critical role in the efficient control of major diseases, both in humans and animals. These classic vaccines were mainly generated using inactivated or live attenuated organisms. More recently, a new generation of well-defined, safer, and effective vaccines has emerged, which is based on the use of recombinant technology and/or subcellular components.

1 Bacterial Vaccines: Introductory Remarks

The successful control of bacterial infections depends on two opposing forces: on the one hand, host-specific and unspecific defense mechanisms, which are designed to restrict bacterial survival and multiplication; on the other hand, the coordinated expression of bacterial virulence factors, which are responsible for their subversion and/or circumvention. The host immune system provides two different lines of defense against infectious agents. The first nonspecific defense line is given by the innate immune system, and the pathogen-specific adaptive immune response constitutes the second. Cellular components of the innate immune system also represent the critical bridge between these two responses (e.g. dendritic cells).

Vaccination constitutes the most cost-efficient strategy for preventing bacterial diseases through the stimulation of pathogen-specific adaptive responses, which are able to protect against subsequent challenge. Most bacterial pathogens are either restricted to the mucosae or need to transit across them to cause disease. Thus, elicitation of a local mucosal immune response after vaccination represents a clear advantage. In fact, the stimulation of a potent local response at the site at which the first line of defense is laid allows promoting protection against both disease and infection (i.e. colonization), thereby reducing the risk of pathogen transmission to other susceptible hosts.

Human vaccination against bacterial diseases has been practiced with success for many years. Despite this success, however, human society continues to suffer millions of deaths and multibillion dollar economic losses annually due to bacterial diseases. This is in part due to the lack of vaccines against many diseases, as well as to the fact that not all available vaccines are completely satisfactory in terms of immunogenicity, efficacy, and safety. In addition, not all efficacious vaccines are used properly. Antivaccine movements in developed countries and economic constraints in the developing world prevent optimal vaccine use. To reduce these losses, there is a critical need to develop new, better, safer, and cheaper vaccines, which are able to promote long-lasting immune responses.

Various strategies have been exploited to develop antibacterial vaccines (Fig. 1). Whole-cell vaccines are produced by inactivating the virulent organisms (e.g. by chemicals, heat). Alternatively, bacteria can be attenuated in such a way that the organisms are not able to cause disease in their natural hosts, but are still able to induce protective immunity. Thus, attenuated organisms are not able to produce clinical disease, but they retain the ability for transient colonization and/or self-limiting replication. These attenuated bacteria can also be used as live carriers (i.e. bacterial vectors) for the delivery of heterologous antigens from other pathogenic organisms. It is also possible to use organisms from a related but nonpathogenic species, as an alternative to attenuated organisms. However, it is essential that they share enough similarity to promote a cross-protective immune response. In other cases, mixed approaches have been established, such as the use of a microorganism from a different species that has been attenuated (e.g. attenuated *Mycobacterium bovis* BCG to protect against tuberculosis). Purified subcellular components from pathogenic

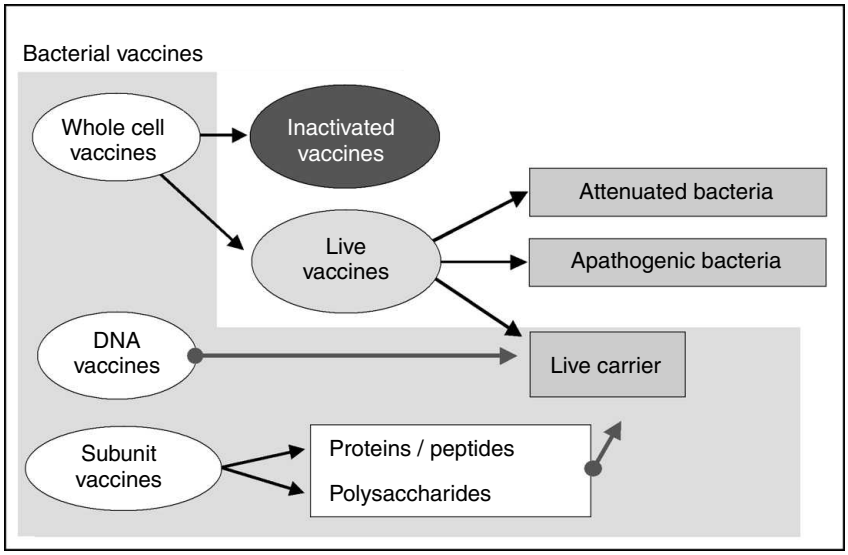

Fig. 1 Main vaccination strategies.

bacteria, which are critical targets for the elicitation of protective responses, can also be used to develop subunit vaccines. Subunit vaccine components can be inactivated toxins, capsular polysaccharides, structural proteins, or nonstructural components. The antigens used can be native or obtained by recombinant DNA technology. Subunit vaccines usually exhibit a better safety profile than whole-cell vaccines. However, they are often less immunogenic, have higher production costs, and demand expensive storage procedures.

A new approach has emerged in the vaccinology field in the last decade, the so-called *DNA vaccines*. This approach consists of the use of eukaryotic expression vectors encoding the antigen of interest, which are delivered to the vaccinees. Then, the biosynthetic machinery of the eukaryotic cells is responsible for synthesis of the vaccine-specific antigens. More recently, attenuated bacteria have been successfully exploited as a delivery system for DNA vaccines against both infectious agents and tumors. The availability of different mutants and highly sophisticated expression tools, as well as the possibility to coadminister immune modulators (e.g. cytokines) allow predictable immune responses to be triggered, according to the specific needs.

2 Inactivated Vaccines

Many vaccines against human or animal infectious diseases are composed of whole organisms, which have been inactivated to prevent *in vivo* multiplication, but retain their immunogenicity. Many of them have been empirically designed, without having a clear understanding of either the protective antigens or the immune protective mechanisms. Furthermore, these vaccines are generally associated with a high incidence of side effects.

2.1 Methods of Inactivation

Whole-cell vaccines are usually inactivated by heating and/or treating with chemicals, and the final vaccine preparation does not usually undergo further purification. Formaldehyde was the reagent first used for chemical inactivation, but glutaraldehyde and phenol have also been used. However, this procedure may affect the immunogenic epitopes present in the antigens. The use of colicin E2, a potent DNA endonuclease that enters target bacterial cells without disrupting cellular integrity, has also been proposed for bacterial inactivation.

A special inactivation approach is based on the use of phage lysis systems. The controlled expression of PhiX174 gene E in gram-negative bacteria results in the formation of a transmembrane tunnel through the cell envelope complex. The resulting so-called *bacterial ghosts* have intact envelope structures, but are devoid of cytoplasmic contents. This process was successfully exploited in a variety of gram-negative bacteria, including *Escherichia coli*, *Salmonella* spp., *Vibrio cholera*, and *Actinobacillus pleuropneumoniae*. The well-preserved surface structures of bacterial ghosts stimulate efficient immune responses when administered by various routes. This seems to be due, at least in part, to the specific targeting of antigen-presenting cells, in which they promote maturation through the potent danger signal delivered by their structural components (e.g. lipopolysaccharides). Ghosts can be used not only as vaccines against diseases caused by the inactivated microorganisms but also as a technology platform for antigen delivery. In this approach, they can be directly loaded with antigens or, alternatively, recombinant antigens can be expressed before lysis.

2.2 Advantages and Limitations of Inactivated Vaccines

Efficient bacterial inactivation leads to vaccine candidates with an extremely good safety profile, which can be administered even to immune-deficient individuals. However, nonreplicating organisms are generally less immunogenic than live bacteria, and multiple doses are required (Table 1). On the other hand, all virulence factors can be expressed by the strain used in the preparation of the vaccine, whereas key virulence factors may be missing in the attenuated vaccine strain. However, *in vitro* cultivation of bacteria does not necessarily lead to the expression of all virulence factors, whereas live vaccines are capable of eliciting immune responses also against *in vivo* expressed antigens. The reactogenicity of inactivated and live vaccines is usually greater than that of other types of vaccines (e.g. subunit vaccines). Vaccines may loose efficacy as a result of accumulated mutations in circulating strains of pathogens. This risk is lower for inactivated than for subunit vaccines, due to the presence of all potential antigens from the pathogen. However, the presence of multiple antigens may result in reduced vaccine efficacy, due to the suppression of immune responses against subdominant antigens by the immune dominants. In contrast to live vaccines, in which the immune response closely resembles that against natural infection, the immune responses against parenterally administered inactivated vaccine are limited to the systemic compartment. In addition, humoral rather than cellular responses are stimulated. Finally, inactivated vaccines are not

Tab. 1 Comparison of live and killed whole-cell vaccines.

Live/attenuated vaccines	*Killed/inactivated vaccines*
Attenuated microorganisms are used	Virulent bacteria can be used
Replicate in the host	Do not replicate
Single or few doses are required	Multiple doses are required
Smaller number of microorganisms	Larger number of microorganisms
Less stable	More stable
No adjuvants are required	Adjuvants often required
Can be delivered by natural infection route	Generally given by parenteral route
Stimulate antibody and cellular responses	Induce good humoral but poor cellular responses
Promote cellular and humoral memory	Stimulate weaker cellular memory
Sometimes spread from vaccinated to unvaccinated individuals	No spread to unvaccinated individuals
Variable safety in immunocompromised patients	Excellent safety in immunodeficient patients
Shorter shelf-life	Usually longer shelf-life
Easy transport and storage	Easy transport and storage
Higher development costs	Lower development costs

shed; thus, they are unable to infect unvaccinated individuals. On the one hand, they do not lead to herd immunity. On the other hand, they do not represent a risk for immunosuppressed contacts. Finally, the development costs of inactivated vaccines are usually lower than those of live or subunit vaccines. However, quality control (e.g. potency tests, killing tests) of inactivated vaccines may be very difficult.

3 Live Vaccines

Live vaccines lead to a self-limited asymptomatic infection, thereby stimulating similar immune responses to those observed after natural infections. Therefore, this kind of vaccine closely matches some of the criteria for an ideal vaccine, since it stimulates long-lasting protection with minimal reactogenicity after a single or a few doses.

3.1 Attenuation

Attenuation of the microorganism eliminates its disease-causing capacity and can be obtained by biological or technical manipulations (e.g. multiple passages through unusual hosts, growth at suboptimal conditions, chemical mutagenesis). In the past, attenuation was performed by empirical techniques. However, the explosive development of our knowledge in the fields of microbial pathogenesis and recombinant DNA technology allows the identification of molecular targets for attenuation and thereby enables rational and precise construction of vaccine strains containing well-defined deletions in these genes. In strains generated by recombinant DNA technology, the attenuation should be sufficient to limit pathogenicity without risk of reverting to the wild-type phenotype. Thus, it is desirable to introduce at least two independent attenuating mutations. The attenuation should not rely

on a fully functional host immune system. Furthermore, it must not be reversible by diet or by host modification of diet constituents, including the host's resident microbial flora. Finally, it is also necessary that the attenuation does not induce a persistent carrier state in vaccinees.

3.2 Advantages and Limitations of Live Bacterial Vaccines

Live vaccines have several advantages and disadvantages in comparison to subunit vaccines (Table 2). Although live attenuated vaccines replicate in the host, subunit or inactivated vaccines are unable to replicate. Therefore, attenuated vaccines usually promote long-lasting immune responses, which mimic those obtained after natural infections. However, the presence of preexisting or cross-reactive immune responses against the vaccine strain may affect its overall efficacy. Live vaccines are less stable and may be easily damaged or destroyed by heat or light. However, cold storage is required for all vaccines registered up to now. Depending on the degree of attenuation and the specific vaccine, multiple doses may be required. The risk of reversion to the wild-type phenotype, which was certainly an issue with the undefined first-generation attenuated vaccines, is now made negligible by the introduction of multiple well-defined independent deletions in second-generation vaccines. However, live vaccines can generally be considered more reactogenic. This also depends on the route of administration, since oral attenuated vaccines against typhoid fever are less reactogenic than parenteral ones. A specific issue to be taken into consideration is the potential risk associated with administration or transmission (i.e. shedding) to immunodeficient individuals. In addition, a careful and exhaustive evaluation of the potential impact of environmental release, including duration and rate of shedding, as well as the risk of horizontal gene transfer, needs to be carried out. A clear advantage of attenuated vaccines is the fact that they have lower production costs than subunit vaccines. In addition, technology transfer to developing countries is facilitated by the simplicity of the upstream and downstream processes. They are also associated with much simpler and less expensive

Tab. 2 Comparison of live and subunit vaccines.

Live vaccines	*Subunit vaccines*
Live/attenuated microorganisms	Subcellular components of microorganisms
Replicate in the host	Do not replicate in the host
Variable safety	Excellent safety
Can spread to unvaccinated individuals	Not transmissible to contacts
Potential risk of reversion	No risk of reversion
Potential risk to immunosuppressed patients	No risk to immunosuppressed patients
Usually more reactogenic	Usually less reactogenic
Stimulate humoral and cellular responses	Trigger mainly humoral responses
May require fewer doses	Multiple doses are required
Generally long-lasting protection	Periodic boosters required
Lower production costs	Higher production costs
Easy administration logistics	More complicated/expensive administration logistics

administration logistics when they are given via the mucosal route. The mucosal route also provides better safety, since parenteral vaccination is an important cause of spreading of HIV and hepatitis in the developing world.

4
Vaccines for Human Bacterial Diseases

Bacterial infections play a major role in human disease. Although the development and use of anti-infective agents has resulted in reduced morbidity and mortality, increases in antibiotic resistance complicate the clinical management of infected patients. Furthermore, the implementation of therapeutic approaches does not reduce the human suffering and costs associated with disease. Vaccines have played a major role in the fight against bacterial diseases that have cost mankind heavily in terms of human lives, such as diphtheria, tetanus, whooping cough, meningitis, and tuberculosis. Thus, it is necessary to foster the use of available vaccines and to develop new ones against those diseases for which no vaccine is yet available.

4.1
Anthrax (*Bacillus anthracis*)

Anthrax is primarily a disease of herbivorous animals acquired via the ingestion of *Bacillus anthracis* spores. Humans occasionally acquire the disease through contact with infected animals or contaminated animal products via the skin (95%) or by ingestion or inhalation. Without treatment, the cutaneous forms of anthrax have 20% mortality, whereas gastrointestinal and pulmonary anthrax reach mortality rates of 25 to 75% and more than 80% respectively. The emerging threat of bioterrorism has awakened the general interest in both the pathogenesis of *B. anthracis* and vaccine development.

Factors contributing to the pathogenesis process are the plasmid (pXO1 and pXO2) – encoded capsule components, the protective antigen, the lethal factor (LF), and the edema factor (EF). The capsule helps the bacterium to evade immune clearance, and the toxins are responsible for inducing edema and shock. Anthrax was the first bacterial disease for which vaccination was successfully demonstrated. In 1881, Pasteur observed protection in sheep after injection of a heat-attenuated *B. anthracis* strain. In 1937, the Sterne vaccine strain was developed, which is nonencapsulated (cured from pXO2) but retains the toxins. The worldwide implementation of this vaccine has contributed to the successful control of the disease in livestock and wild animals. However, it cannot be used in sensitive animals, due to its residual virulence. More recently, several live vaccine candidates lacking EF and LF were developed. However, they were considered not suitable for human use, since they still retain a certain degree of virulence. In 1970, an anthrax vaccine was licensed for human use, which consists of a sterile filtrate of microaerophilic cultures of a nonencapsulated avirulent strain.

4.2
Cholera (*Vibrio cholerae*)

Cholera is a serious water- and foodborne epidemic disease caused by *V. cholerae*, which has killed millions of people and continues to be a major health problem worldwide. Bacteria colonize the small intestine and produce an exotoxin, cholera toxin (CT), consisting of an enzymatically active subunit A and five identical

B subunits. CT disrupts the function of ion pumps, leading to changes in the net flows of sodium, chloride, and water, and resulting in massive diarrhea, electrolyte imbalance, and circulatory collapse. According to the lipopolysaccharide (LPS), two serogroups are circulating (O1 and O139). O1 organisms are classified as classical or El Tor biotypes, according to the phenotype. *V. cholerae* O1 El Tor biotype is the predominant cause of cholera worldwide; however, a minority of cholera cases are caused by *V. cholerae* O139.

Convalescents develop a protective immune response, as demonstrated by both volunteer studies and patients follow-up. Serological responses against LPS and CT are observed after a cholera episode, and can block colonization and neutralize CT. The first recorded attempt to develop a vaccine against cholera was in the late 1880s. This killed whole-cell vaccine was injected into the bloodstream, but failed to elicit protective immunity and was associated with high rates of side effects. However, a phenol-killed *V. cholerae* Ogawa and Inaba vaccine administered by parenteral route is licensed, which stimulates high titers of vibriocidal antibodies in 50 to 90% of vaccinees and shows an efficacy of about 50% for about 6 months.

To obtain a good local immune response in the gut, an oral vaccine based on heat-killed classic Inaba and Ogawa and formalin-killed El Tor Inaba and classic Ogawa, coadministered with 1 mg of the CT B subunit (CTB), has been developed and showed 60 to 85% efficacy in humans. Another oral vaccine is based on a genetically attenuated *V. cholerae* O1 classical Inaba strain (CVD 103-Hg®), contains a deletion in the CT enzymatically active subunit, and has been marked with a gene coding for mercury resistance that permits differentiation between recombinant and wild-type circulating isolates. This vaccine was licensed in Switzerland in 1994 and is now also available in several other countries. Placebo-controlled trials in several countries have shown the safety and immunogenicity of a single dose of CVD 103-Hg®, even in HIV-infected individuals. Side effects, such as mild nausea, abdominal cramping, and diarrhea, were rarely observed. A single dose conferred 95 and 65% protection against *V. cholerae* classical and El Tor, respectively, in volunteers in challenge studies. Another candidate vaccine is the *V. cholerae* O1 El Tor Inaba Peru-15 strain, which was obtained by incorporating a series of genetic deletions and modifications. A seroconversion rate of 97% for vibriocidal antibodies was observed, and none of the volunteers showed moderate or severe diarrhea after challenge with *V. cholerae* O1 El Tor Inaba strain. None of these vaccines is expected to confer protection against *V. cholerae* O139. However, candidates based on these approaches against O139-expressing *V. cholerae* are being developed.

4.3 Enterotoxigenic *Escherichia coli*

Enterotoxigenic *E. coli* (ETEC) is the most common cause of traveler's diarrhea, which is acquired by ingestion of contaminated food or water. Whole-cell vaccines, which mimic natural infections, seem to promote longer immunoprotection and are being evaluated in clinical trials. A nonreplicating whole-cell anti-ETEC vaccine was prepared by treating the enterotoxigenic *E. coli* strain H-10407 (O78:H11, CFA/I), which produces heat-stable and heat-labile (LT) toxins, with colicin E2. After two oral doses, 77.3 and 86.4% of the volunteers showed anti-CFA/I and anti-LT sIgA responses, respectively, and

90% showed antibodies to CFA/I, LT, or both. On the other hand, a formalin-killed oral ETEC vaccine expressing the most common colonization-factor antigens (i.e. CFA/I, CFA/II, and CFA/IV) and recombinant CTB was given to volunteers in Sweden. An increment in IgA-secreting cells and in the levels of intestinal sIgA against CTB and various CFA components were detected in the majority of volunteers after two doses. Oral vaccination with a killed ETEC plus CTB vaccine in Egyptian children evoked a fourfold rise in antitoxic IgA and IgG titers in 93 and 81% of the vaccinees. The vaccine was also safe and immunogenic in 2- to 12-year-old children. Besides the use of whole-cell *E. coli* vaccines, other approaches have been pursued to stimulate efficient anti-ETEC immune responses, such as the use of purified fimbriae, toxoids, or carrier organisms expressing ETEC antigens.

4.4 Plague (*Yersinia pestis*)

Yersinia pestis is the etiological agent of plague, a disease that has caused over 200 million human deaths. Plague is primarily a disease of rodents, but it can also affect humans. Three main forms of plague occur in humans: bubonic, septicemic, and pneumonic. The common form is bubonic plague, which arises following a bite from a flea that previously fed on an infected animal. The most-feared form is pneumonic plague, which is transmitted from person to person via droplets and has mortality rates of up to 100%. To prevent the disease, both killed whole-cell and live attenuated vaccines have been used. Killed *Y. pestis* bacteria have been used as veterinary vaccines since 1897, and the first killed vaccine for human use was developed in 1946. Various methods have been exploited for inactivation, including formaldehyde and heat treatment. The Commonwealth Serum Laboratories are currently producing a heat-killed *Y. pestis* vaccine (strain 195/P), which is given subcutaneously in three doses over a period of 2 months. This vaccine is mainly used in individuals who may be exposed to the pathogen, for example, veterinarians, researchers, and persons who are deployed to work in areas where the disease is endemic. However, 10% of immunized individuals show side effects such as malaise, headache, fever, and lymphadenopathy. In addition, no clinical trials have demonstrated the efficacy of killed whole-cell vaccines, and some studies suggest that killed vaccines do not provide protection against pneumonic plague.

A live attenuated strain of *Y. pestis* (EV76) was derived from a fully virulent strain by *in vitro* passages. The vaccine has been in use since 1908, especially in the former Soviet Union and the French colonies. Studies in mice indicate that this vaccine provides protection against bubonic and pneumonic plague. However, the safety of this vaccine in humans is questionable. In recent years, we have seen a renewed interest in the development of efficient and safer vaccines against this old pathogen, due to the potential risk of illegitimate use of *Y. pestis* as a biological weapon.

4.5 Shigellosis (*Shigella* species)

Shigellosisis a diarrheal disease, which is transmitted via contaminated food and water or through person–to–person contact. As few as 10 organisms can cause infection, leading to diarrhea or dysentery with frequent mucous bloody stools and severe abdominal cramps. Shigellosis is caused by four main species,

Shigella flexneri, the most common in endemic areas; *Shigella dysenteriae* type 1, most frequent in overcrowded areas and associated with large epidemic outbreaks; *Shigella sonnei*, more active in developed countries; and *Shigella boydii*. Infections caused by *S. dysenteriae* type 1 can also lead to severe complications, such as hemolytic-uremic syndrome. Between 1966 and 1997, the annual number of *Shigella* episodes worldwide was estimated to be 164.7 million, 69% of them being children under the age of 5. Approximately 500 000 deaths occur each year due to this disease.

Soon after isolation of *S. dysenteriae* in 1898, heat-killed cultures were tested to assess their potential as vaccines. However, there is still no vaccine available to prevent *Shigella* infections. In 1950, the first efforts to develop an attenuated vaccine strain were undertaken. The strains T32-ISTRATI, which was isolated after 32 passages on nutrient agar, and *S. flexneri* 2a SmD, which was dependent on streptomycin, yielded promising results, but they were associated with side effects. Subsequent efforts were focused on the use of a hybrid *E. coli* K-12 containing the invasion plasmid that codes for somatic antigens of *S. flexneri* 2a (*E. coli* EcSf2a-2 hybrid). More recently, work has addressed the development of recombinant strains containing mutations in the genes responsible for the biosynthesis of essential aromatic compounds (e.g. *aroA, aroD*) and/or virulence factors (*icsA, iuc, virG, sen, set, stxAB*). These mutants undergo only minimal intracellular replication or are deficient in intracellular and cell-to-cell spread. Promising results were obtained in clinical trials with volunteers after vaccination with some of these candidates. Finally, subunit vaccines, such as O antigen coupled to a carrier protein (conjugate vaccines), vesicles of *Neisseria* outer-membrane proteins and O-polysaccharide (proteosome vaccines), and noncovalent complexes of O-polysaccharide and ribosomal particles (ribosomal vaccines) also gave encouraging results in preclinical and clinical studies.

4.6 Tuberculosis (*Mycobacterium tuberculosis*)

Mycobacterium tuberculosis remains a major health problem worldwide, with about 2 million people dying of tuberculosis each year. *M. bovis* Bacillus Calmette–Guérin (BCG), is the only available vaccine against tuberculosis and constitutes the most widely used live bacterial vaccine in the world. The original strain was attenuated by performing >200 successive *in vitro* passages over 13 years. This strain was then distributed to several laboratories worldwide, where it was produced and maintained. Of the vaccines currently in use, more than 90% belong to 4 main strains: the French Pasteur strain 1173 P2, the Danish strain 1331, the Glaxo strain 1077, and the Tokyo strain 172. Despite the WHO's attempts to standardize production and vaccine characteristics, the concentration ranges from 50 000 to 3 million bacteria per dose. Some vaccines (Pasteur 1173 P2 and Danish 1331) induce strong immunogenicity in animal models, whereas the strains Glaxo 1077 and Tokyo 172 stimulate weak responses. Side effects differ from strain to strain and are predominantly related to infection or to errors in achieving intradermal inoculation (e.g. local reactions, lymphadenitis, osteitis). Recently, the BCG strains have been carefully characterized and shown to lack expression of certain antigens present in *M. tuberculosis*, which might be important for protective immunity. Therefore,

BCG is the most controversial vaccine in current use. It is generally accepted that BCG protects children from meningeal and miliary tuberculosis. However, protection of adults from the most common form of the disease, pulmonary tuberculosis, varies in different studies from 80% in the United Kingdom to 0% in South India. This variable efficacy can be due to many reasons, such as vaccine strain, vaccine quality, host genetics, nutrition, exposure of the vaccine to UV, infection incidence, and clinical study protocols. Fundamental questions need to be addressed concerning the rational design of novel tuberculosis vaccines, preclinical and clinical tests, and future implementation in the field.

4.7 Typhoid Fever (*Salmonella enterica* serovar Typhi)

Typhoid fever affects about 17 million people worldwide each year, with approximately 600 000 deaths. The disease is caused by *Salmonella enterica* serovar Typhi, after ingestion of contaminated food or water. Typhoid fever and infections caused by other serovars in humans and animals are a serious medical and veterinary problem (see Sect. 5.5). Thus, the development of vaccines against this pathogen has constituted an important focus of research. Whole-cell inactivated or attenuated vaccines, as well as subunit vaccines, have been used with variable results. However, most licensed typhoid vaccines confer only about 70% protection, show poor efficacy in young children, and are not used for routine vaccination.

The first parenteral whole-cell typhoid fever vaccine was introduced in 1896 in England. Using heat, alcohol, acetone, or formalin, different whole-cell vaccines were constructed and tested in field trials. These vaccines conferred 51 to 88% protection to children and young adults, lasting for up to 12 years. However, inactivated vaccines often lead to local and systemic side effects, such as fever (6–30%), headache (10%), and severe local pain (up to 35%). This type of vaccine also requires regular boosts; thus, they are rarely included in public health programs. The first human trials using attenuated strains against salmonellosis were made in the early 1970s with a streptomycin-dependent mutant of serovar Typhi. However, no significant protection was conferred by this vaccine. Then, a live attenuated vaccine strain (Ty21a) was developed by chemical mutagenesis. This strain is administered by the oral route and carries, among others, the *galE* mutation, which renders bacteria extremely susceptible to lysis in the presence of galactose. Ty21a constitutes one of the few licensed attenuated bacterial vaccines for human use and the only live vaccine against serovar Typhi. Two different formulations of Ty21a live oral typhoid vaccine have been commercialized. The liquid formulation provides better protection than enteric-coated capsules. Three doses of Ty21a in liquid formulation stimulated 77% protection over three years and 78% over five years of follow-up. Ty21a caused minimal side effects, with nausea being the only adverse event appearing more frequently in vaccinees than in the control group. A postmarketing surveillance study showed only 743 spontaneous reports of adverse effects in more than 38 million vaccinees. On the other hand, a parenteral subunit vaccine based on purified capsular polysaccharide (Vi antigen) was shown to provide 64 to 72% protection over 21 months. A conjugate of Vi with nontoxic recombinant *Pseudomonas*

aeruginosa exotoxin A (rEPA) showed enhanced immunogenicity in adults and also in children 5 to 14 years of age and stimulated a booster response in 2- to 4-year-old children. Interestingly, an efficacy of over 90% in 2- to 5-year-old children was reported after intradermal immunization with the Vi-rEPA conjugate vaccine. The improved knowledge of bacterial physiology, pathogenesis mechanisms, and host immune response has allowed developing a new generation of live attenuated vaccine strains. They have been generated by introducing defined nonreverting mutations into genes coding for metabolic or virulence functions. These vaccines have given promising results in preclinical and clinical studies.

4.8 Tularemia (*Francisella tularensis*)

Tularemia, caused by *Francisella tularensis*, is a primary disease of a wide variety of wild mammals and birds, but it can also be transmitted to humans. Type A strains of *F. tularensis* found in North America are more virulent than type B strains found in Asia, Europe, and North America. Human infections can be caused by as few as 10 bacteria, which enter the host via the skin, mucous membranes, gastrointestinal tract, or the lungs. The high disease incidence in the United States and Russia during the first half of the 20th century led to intensive research aimed at the development of efficient vaccines, because it was observed that previously infected individuals were protected against reinfection. However, vaccine candidate strains inactivated by heat, acetone, or phenol treatment did not show satisfactory efficacy in animal studies or human volunteers. During the same period, the Soviet Union developed attenuated strains, which were used to immunize millions of individuals living in tularemia-endemic areas by intradermal route until 1960. Attenuation was obtained by repeated subculturing in media supplemented with antiserum. One of those attenuated strains, *F. tularensis* LSV, was brought to the United States in 1956, and was routinely used to protect technical personnel against laboratory-acquired infections. *F. tularensis* has been considered a potential biological weapon since 1932. Because of the current danger of bioterrorism, the LSV vaccine is currently under review by the US Food and Drug Administration to assess its future potential as a vaccine.

4.9 Whooping Cough (*Bordetella pertussis*)

Whooping cough is a highly contagious respiratory infection caused by the gram-negative bacillus *Bordetella pertussis*. This pathogen still remains an important killer of children, although there has been a global decline in incidence, consistent with the overall increase in immunization. In 2001, over 12 million cases of pertussis were estimated to occur worldwide, which led to more than 285 000 deaths. After the isolation and propagation of the causative agent in 1906, major efforts were focused in the development of a vaccine. In 1914, a whole-cell ''whooping cough vaccine'' was listed in the United States. Over the following decades, several whole-cell vaccines were generated, which consist of chemically or heat-killed *B. pertussis* cells. In 1942, the inactivated whole-cell *B. pertussis* vaccine was combined with diphtheria and tetanus toxoids, leading to a triple vaccine (DTP) that is still in use and confers more than 80% protection. The incidence of whooping cough has been

greatly reduced by mass immunization with DTP.

Whole-cell vaccines were frequently associated with local side effects (pain, redness, swelling). Some children also showed transient fever, protracted inconsolable crying, hypotonic–hyporesponsive episodes, and seizures. Additional studies showed that the vaccine does not cause sudden infant death syndrome, spasms, or epilepsy and that the risk of developing an acute encephalopathy was less than 1 : 100 000. Thus, the benefits associated with whole-cell vaccines clearly outweigh the risks of side effects, and vaccine-mediated neurological damage or death has never been conclusively proven. However, increasing concern about adverse effects has led to a reduction in public vaccine acceptance and a consequent increase in the incidence of the disease. Thus, efforts were made to develop acellular subunit vaccines against whooping cough based on key virulence factors (pertussis toxoid, pertactin, filamentous hemagglutinin), which are now in the market. These vaccines show much lower rates of adverse effects and have replaced whole-cell vaccines in developed countries. However, due to their lower costs, whole-cell vaccines are still used in developing countries. One of the major advantages of subunit vaccines is that they can be also used in older children and adults. Thus, they are particularly useful for boosting. This is particularly important, because both natural infection and vaccination with whole-cell or acellular vaccines induce protection against reinfection only for a limited time (about 5–15 years). Adolescents and adults become gradually susceptible, as demonstrated by the increased incidence of atypical whooping cough cases in these age groups.

5 Veterinary Bacterial Vaccines

Bacterial pathogens cause a wide range of diseases in animals and have a tremendous economic impact. In addition, individuals with occupational or chronic exposure can acquire zoonotic disease (e.g. veterinarians, farm workers, butchers, pet owners). Thus, animal diseases should be combated both to improve the quality of animal products and to prevent human disease. The use of antibiotics does not constitute a valid alternative, due to both actual regulations for human food and the increased risk of emergence of antibiotic resistance. Therefore, vaccination is the best alternative for tackling this problem. The use of vaccines allows reduction of (1) the clinical symptoms and the consequent economic impact of veterinary diseases, (2) the risk of carrier development, and (3) bacterial shedding and horizontal transfer to susceptible hosts.

Since the early 1900s, massive research efforts have been invested in preventing bacterial diseases in animals. Incomplete knowledge of the causative agents and limited information about clearance mechanisms rendered this task difficult. However, by the end of the twentieth century the use of bacterial vaccines has led to a significant reduction in the incidence of infectious diseases in the veterinary field. Thus, there are many examples of veterinary diseases for which vaccines were successfully implemented. Interestingly, the number of inactivated or attenuated classical bacterial vaccines is consistently larger in the veterinary than in the human field. This is due, at least in part, to broader margins in terms of acceptable side effects and to the critical need of keeping costs low. Furthermore, combined formulations containing different bacterial and/or viral

components are the rule rather than the exception. Although the presentation of a fully comprehensive report of all veterinary vaccines goes beyond the scope of this article, several examples are given below. The focus is on those diseases that have the biggest impact, with particular emphasis on those for which classical bacterial vaccines have been introduced into the market.

5.1 Infections Caused by *Bordetella* and *Pasteurella* species

Symptomatic and asymptomatic infections caused by *Bordetella bronchiseptica* are extremely widespread in the veterinary field, with infection rates that may reach 80 to 100% in intensively reared animals. This microorganism produces a variety of pathological syndromes and predisposes infected animals to viral or bacterial superinfections (e.g. *Pasteurella multocida* Type D and *Mycoplasma hyopneumoniae* in pigs). Pigs infected with *B. bronchiseptica* and toxigenic strains of *P. multocida* can develop atrophic rhinitis. The dermonecrotic toxin released by *P. multocida* affects osteocytes and osteoblasts, promoting bone resorption and leading to systemic manifestations, and is responsible for progressive atrophic rhinitis. The signs of the disease appear by 8 to 12 weeks of age and progress throughout the growing period. Infected animals show severe atrophy of the nasal turbinate bones, accompanied by lateral deviation or shortening of the nose. A British survey on abattoir pigs showed that 92% of herds were infected, with 36% of animals exhibiting atrophic changes. This may result in a 5 to 15% reduction on live weight gain (25–40 g/day), which in turn may lead to an annual loss of output or resource wastage of 1 to 4 million £. Thus, parenteral vaccines against atrophic rhinitis, which are based on inactivated *B. bronchiseptica* in combination with *P. multocida* Type D dermonecrotic toxoid alone or together with chemically inactivated *Pasteurella*, are widely used in pigs. Vaccinated animals and their progeny develop high titers of antibodies against *B. bronchiseptica* and *P. multocida* dermonecrotic toxoid. Both sows and gilts and their piglets are vaccinated, leading to reduced bacterial colonization, toxin neutralization, better growth, increased average daily weight gain (ADG), better snout scores, and reduced mortality. In some cases, these vaccines are combined with inactivated *Erysipelothrix rhusiopathiae* to prevent erysipelas in sow herds. In addition to inactivated *B. bronchiseptica* vaccines for pigs, field studies have been performed with live attenuated prototypes, which stimulate immune responses that can reduce morbidity rates relative to unvaccinated controls.

Vaccines against *Bordetella* spp. and *Pasteurella* spp. have also been developed for other animal species. Among them, attenuated *B. bronchiseptica* vaccines, for intranasal administration to dogs to prevent infectious tracheobronchitis (kennel cough), are generally combined with other antigens (e.g. attenuated canine parainfluenza virus). Live attenuated vaccines against the poultry pathogen *Bordetella avium* were introduced into the market to protect turkeys against rhinotracheitis.

Pasteurella pneumonia is estimated to be the top killer of cattle in the United States, and *Pasteurella haemolytica* is the main contributor to shipping fever, costing millions of dollars annually in deaths and treatment costs. Thus, attenuated *P. multocida* strains are combined with *P. haemolytica* in formulations for cattle. Viral components, such as rhinotracheitis

virus, bovine respiratory syncytial virus, parainfluenza, and bovine diarrhea virus are added to the basic formulations to cover a broad range of pathogens.

Infections of domestic and wild birds with *P. multocida* lead to fowl cholera, a contagious, widely distributed disease with high morbidity and mortality. The disease is typically characterized by sudden septicemia and fibrinous pneumonia; however, chronic and asymptomatic infections also occur. *P. multocida* subspecies *multocida* is the most common cause of fowl cholera, although subspecies *septica* and *gallicida* may also cause a fowl cholera-like disease. *P. multocida* is classified into 16 serotypes based on its lipopolysaccharide antigens, and the strains most frequently causing fowl cholera are A:1, A:3, and A:4. Live attenuated and inactivated (e.g. Cholervac-PM-1®) *P. multocida* vaccines have been introduced into the market. Whole-cell inactivated vaccines (bacterins) can provide protection, but only against the homologous serotype. On the other hand, live attenuated vaccines can protect under *in vivo* conditions against heterologous serotypes. However, attenuated vaccines retain a low level of virulence, and these strains can be implicated in infection outbreaks. For the prevention of fowl cholera, the most commonly used live vaccines are the *P. multocida* M-9 and PM-1 strains. Current experimental studies revolve around identification of the specific cross-protective antigens that might be incorporated into vaccine formulations, such as the outer membrane protein Oma87, a type-4 fimbrial subunit (PtfA), and a transferrin binding protein (Tbpl). Although conclusive evidence concerning a potential role of the capsule in virulence is still missing, the genes involved in capsule biosynthesis have been characterized as potential attenuation targets. More recently, attenuated auxotrophic *P. multocida aroA* derivatives have been generated by recombinant DNA technologies and are able to protect against homologous and heterologous challenges in chickens.

5.2 Brucellosis (*Brucella* spp.)

Brucellosis is a worldwide distributed zoonotic disease caused by *Brucella* spp. Infective cells can persist in the environment for weeks, and dried preparations can retain virulence for years. *B. melitensis* commonly infects goats and sheep and is particularly virulent in humans, whereas *B. abortus, B. ovis,* and *B. suis* preferentially infect cattle, sheep, and swine, respectively. The disease can be transmitted to humans by consumption of raw animal products or by direct contact with infected animals or their carcasses, through skin lesions or by inhalation.

Because of the serious economic and medical consequences of brucellosis, consistent efforts have been invested to develop vaccines. However, no human vaccine is currently available against brucellosis, and the disease is mainly controlled by animal vaccination. Antibodies and cell-mediated immunity can influence the course of the infection. However, cell-mediated responses (e.g. CTL) are required for clearance of intracellular bacteria. These responses are best stimulated by using live vaccines or by multiple injections of protective antigens with adjuvants. Only a few effective candidates have been identified so far that reduce abortion but not necessarily infection. Live vaccines retain some virulence and, depending on the administered dose, abortions may occur during pregnancy. The strain *B. abortus*

19 has been the most widely used to prevent brucellosis in bovines. However, the efficacy differs according to the age, dose, route of administration, and disease prevalence in vaccinated herds. The strain was originally isolated from cow milk in 1923, and, after being kept at room temperature, it was found to be attenuated. The live attenuated *B. melitensis* strain Rev.1 can stimulate protection against *B. melitensis* in sheep and goats. This strain also protects rams against infection with *B. ovis*. Strains 19 and Rev.1 can be horizontally transferred from vaccinated to unvaccinated animals and change to a rough form, since they persist in some animals. Another disadvantage is that the vaccine strains are fully virulent to humans, and many accidental infections have been reported. Other attenuated strains have not been widely adopted, such as a mucoid derivative of *B. suis* (M vaccine), the *B. abortus* 104-M vaccine, *B. suis* strain 2, and *B. melitensis* strain 5, which were used as oral vaccines in China.

The smooth vaccine strains 19 and Rev.1 stimulate anti-O-chain antibodies, thereby preventing differentiation between vaccinated and infected animals. Therefore, efforts were addressed toward the development of a marker vaccine that would not interfere with eradication programs. The smooth *B. abortus* strain 45/20 was isolated in 1922 and became rough after 20 passages in Guinea pigs. This strain was protective but tended to revert to the virulent form. Thus, it was used as an inactivated preparation with adjuvants based on water and oil emulsions. However, this vaccine was discontinued because its efficacy varied greatly from batch to batch and was associated with severe local reactions. *B. abortus* strain RB51, which lacks the O-chain, was very stable after multiple *in vitro* and *in vivo* passages. Its efficacy after subcutaneous vaccination was similar to that of strain 19, but so far it has not led to deleterious side effects. Thus, strain RB51, which also induces protection in swine against *B. suis* and in goats against *B. melitensis*, is replacing strain 19 in several countries. Oral vaccination with RB51 stimulates protective immunity in mice and cattle; hence, a practical approach to wildlife immunization seems possible.

Prevention of human brucellosis is best achieved by control or eradication of the disease in animals, combined with adequate heat treatment of potentially contaminated food products. However, in some countries this is not feasible. Therefore, attempts have been made to protect humans by vaccination. This has been reinforced by the renewed interest in *Brucella* resulting from its potential as a biological weapon; however, the results obtained have been generally disappointing. A derivative of strain 19 (19-BA), which was administered by scarification in the former USSR, stimulates short-time protection but leads to severe reactions. Strain RB51 shows minimal pathogenicity in humans, but is resistant to rifampicin, which makes it unsuitable for human use.

5.3 Porcine Pleuropneumonia (*Actinobacillus pleuropneumoniae*)

Actinobacillus pleuropneumoniae is the etiologic agent of a highly contagious porcine pleuropneumonia, characterized by fibrinous, hemorrhagic, and necrotic lung lesions. The disease shows a morbidity of 15 to 30% and is associated with high mortality rates in acute outbreaks (100% of affected pigs) and a decrease in the ADG of up to 35%. So far, 15 serotypes have been identified. Different vaccines have

been introduced into the market; some are based on inactivated bacteria (bacterins), and other formulations are based on purified and detoxified Apx toxins I, II, and III (subunit vaccines). Many of these vaccines are combined with other agents, such as chemically inactivated *E. rhusiopathiae* or *Haemophilus parasuis*. Natural or experimental infection with live bacterial cells seems to offer the greatest level of protection against reinfection, suggesting that a live strain would be the ideal vaccine candidate. Several attenuated *A. pleuropneumoniae* strains have been constructed and conferred various degrees of protection against disease; these included temperature-sensitive, metabolic, nonencapsulated, and nontoxigenic mutants. More recently, an attenuated mutant deficient in the biosynthesis of aromatic compounds (HS25 *aroQ*) has been safely delivered to pigs.

5.4 Diseases Caused by *Mycoplasma* spp.

Mycoplasma spp. cause upper and lower respiratory tract infections in various animal species. These microorganisms contain the smallest bacterial genomes, lack cell walls, and are strictly dependent on the host for survival. *Mycoplasma hyopneumoniae* is a main player in the porcine respiratory disease complex, leading to significant economic losses. The prevalence of enzootic pneumonia ranges from 30 to 80% in different countries. *M. hyopneumoniae* also creates a port of entry for other pathogens. This phenomenon, known as *Mycoplasma-induced respiratory disease* (MIRD), aggravates the seriousness of the clinical signs and increases economic losses. MIRD can considerably affect the feed efficiency index (up to 14%) and the ADG (up to 17.4%). This situation results in an increase in the fattening period, which in turn leads to decreased rotation rates, increased labor and feeding costs, and reduced annual production. Infections spread from the infected sow to its litter and from older to younger susceptible pigs. Commercial vaccines have been available since 1991. They are based on inactivated and adjuvanted bacteria and are administered to baby or feeder pigs, as well as to breeding stocks. Some of the vaccine preparations have been combined with antigens from other pathogens, such as inactivated *E. rhusiopathiae* or *H. parasuis*, the etiologic agent of Glasser disease (i.e. polyserositis).

Mycoplasma gallisepticum is also an important pathogen that causes chronic respiratory disease in chicken. Vaccination with killed or living vaccines is an option for controlling infections in poultry flocks when hygienic measures fail. Live attenuated *M. gallisepticum* vaccines include the strains F, ts-11, and 6/85. The F-strain (administered in drinking water or by aerosol) reduces the decline in egg production but has residual virulence. On the other hand, strain ts-11 is less virulent and immunogenic, but still provides effective long-term protection. Temperature-sensitive mutants of *M. gallisepticum* (TS100) were used to immunize newly hatched chickens and protected them from developing air-sac lesions.

Mycoplasma agalactiae is the causal agent of contagious agalactia in small ruminants. The disease, which is more frequent in the Mediterranean region, North Africa, and the Middle East, is characterized by mastitis, arthritis, and pneumonia. Killed organisms are usually administered in combination with adjuvants. Inactivation with phenol seems to confer better protection than formalin- or heat-inactivation.

The lack of protection observed in the field may be due to infections with other *Mycoplasma* spp. Improved protection in comparison to killed vaccines was observed with live attenuated strains of *M. agalactiae*.

5.5 Salmonellosis in Animals

Salmonella causes diseases characterized by acute or chronic enteritis and septicemia in many animal species, which are the principal reservoirs for human infections. Transmission to humans occurs by contaminated drinking water or food products (e.g. milk, meat, eggs), and their incidence has increased worldwide due to the intensification of livestock production. *S. enterica* serovar Typhimurium became the second most important cause of salmonellosis in humans. Since vaccination is compulsory for poultry meat producers, and EU regulations also require monitoring of broiler-breeder flocks and slaughter of infected flocks, efforts have been made to develop efficacious multivalent vaccines for poultry. One of these vaccines consists of iron-restricted inactivated *S. typhimurium* and *S. enteritidis*. After intramuscular vaccination, chickens are protected against an oral challenge, but colonization still occurs. Other mutants, for example, *dam*, show better results with respect to protection and colonization. The first live oral vaccine against *S. typhimurium* and *S. enteritidis* was launched by Lohmann Animal Health in 2003 (TAD Salmonella). Three doses administered into the birds' drinking water give protection throughout the laying period.

The efficacy of live vaccine candidates against *Salmonella choleraesuis* (e.g. Argus SC), which causes infections in pigs, has also been evaluated. Vaccinated pigs were able to maintain normal weight after challenge, and field studies demonstrated that this type of vaccine can lower the prevalence of *Salmonella* in swine herds.

Salmonella gallinarum and *Salmonella pullorum* cause fowl typhoid and pullorum disease in birds. The clinical manifestations include anorexia, diarrhea, hepatitis, splenitis, myocarditis, pneumonia, ophthalmitis, and high mortality due to septicemia. This leads to decreased egg production and fertility. Thus, inactivated and live attenuated vaccine strains have been developed for poultry. Since 1950, attenuated derivatives of *S. gallinarum* strain 9 have been extensively assessed. One of them was attenuated by passage in a medium of low nutritional quality, leading to the so-called *9R fowl typhoid strain*, which confers strong protection to adult chickens after intramuscular injection. However, this strain retains some virulence, may persist for many months, and can be transmitted through the egg. To obtain a more avirulent strain, an *aro A* mutant was developed, but it was less effective. A single oral immunization with an *S. gallinarum nuoG* derivative reduced the mortality in 2-week-old chickens following challenge with virulent *S. gallinarum* from 75% to less than 8%. Another approach was the intramuscular application of attenuated "phage type" PT4 *S. enteritidis*.

5.6 Leptospirosis (*Leptospira* spp.)

Leptospirosis is one of the most widespread diseases in livestock and is caused by over 250 immunologically distinct serovars. Bacteria are spread by contact with skin or mucous membranes with contaminated products. Infected animals contribute to further

spreading of the disease by actively shedding bacteria. Infections may be asymptomatic or symptomatic (e.g. fever, icterus, hemoglobinuria, renal failure, infertility, abortion, and death). Of the distinct pathogenic serovars, only a small number have been isolated from domestic animals. It is remarkable that only moderate cross-immunity between serovars is observed. Cattle, swine, and horses are the most economically relevant affected species. Because leptospirosis in domestic animals is leading to significant economic losses and infected animals are a potential source of human infection, vaccination with polyvalent vaccines have been widely implemented. Certain occupational groups, such as farmers, sewer workers, and meat workers, have special risks of acquiring the disease. Outdoor leisure activities can also lead to exposure to infection. Inactivated polyvalent vaccines containing different Leptospiras (e.g. *grippotyphosa, hardjo, icterohaemorrhagiae, canicola, pomona*) are commercially available for preventing abortions and stillborns in livestock and pets. Most of them have been combined with components against other pathogens, such as *E. rhusiopathiae*, parvovirus, *Campylobacter*, bovine rhinotracheitis virus, bovine diarrhea virus, and bovine respiratory syncytial virus.

5.7 Other Commercially Relevant Animal Diseases

Vaccines that are able to prevent other diseases in livestock and pets have also been developed and implemented in the field. Among them are inactivated oil-adsorbed vaccines against *Haemophilus paragallinarum*, which is responsible for infectious coryza in chickens. This disease is characterized by swelling of the infraorbital sinuses, facial edema, oculonasal discharge, and sneezing and may cause significant losses in the poultry industry. Inactivated adjuvanted vaccines based on various strains of *Fusobacterium necrophorum* and/or *Bacteroides nodosus* are also available to prevent and treat chronic foot rot in sheep and acute foot rot in cattle. It is also possible to immunize against equine monocytic ehrlichiosis by using a whole-cell inactivated *Ehrlichia risticii* preparation. For pigs, killed vaccines against *Streptococcus suis* have also been developed. In addition, inactivated vaccines that are based on inactivated enterotoxigenic and enteropathogenic *E. coli* combined with toxoids are available for preventing post-weaning diarrhea. *Chlamydia psittaci* is responsible for respiratory infections in cats, leading to serous conjunctivitis, sneezing, and nasal discharge. Vaccinated cats have mild clinical disease and are protected from severe clinical disease after challenge exposure. Owing to the frequent emergence of adverse effects (e.g. lethargy, anorexia, lameness, and fever), the use of vaccines is frequently restricted to cats at risk of exposure. Live attenuated vaccines may cause atypical reactions in about 3% of vaccinated cats. Finally, vaccines have been also developed to prevent bacterial infections in fish. A live attenuated vaccine is used to prevent the enteric septicemia caused by *Edwardsiella ictaluri*, which costs millions of dollars to the catfish industry.

6 Conclusions

During the past 200 years, various vaccines have been developed and exploited to control major diseases. In many instances, however, the exact mechanisms of action

of successful vaccines were not fully understood. A new generation has emerged, of well-defined recombinant and/or subunit vaccines that exhibit a considerably improved safety profile. However, classical bacterial vaccines have not only played a critical role in the efficient control of infectious diseases in the past, they are still instrumental in the prevention of infections both in humans and, particularly, in animal populations.

Keywords

Fitness
An individual's relative success in transmitting his or her genes to the next generation.

Genetic Drift
Random intergenerational change in gene frequencies due to finite population size.

Haplotype
The allelic constitution of several loci on a single chromosome (''haploid genotype'').

Heterozygote Advantage
A fitness differential in which the heterozygote has higher fitness than any of the homozygotes.

Natural Selection
An evolutionary process in which individuals with a specific genetic variant have higher fitness than those lacking the variant.

Polymorphism
The occurrence of two or more alleles at a locus in a population, where at least two alleles occur with frequencies greater than 1%.

Variation in the prevalence of genetic diseases results from the action of the evolutionary processes of mutation, natural selection, genetic drift, and gene flow. Genetic markers can be studied in populations to help determine the ways in which these processes interact to influence disease prevalence. This enhances our understanding of the origins and evolution of genetic diseases. This article will review the ways in which genetic markers are used to study disease variation in populations, using specific genetic diseases as examples.

1 Introduction

The prevalence of many genetic diseases varies widely among human populations (see Fig. 1 for examples). Cystic fibrosis (CF) is the most common lethal single-gene disorder among Caucasians, affecting approximately 1 in 2500 individuals. Yet, it is quite uncommon among Asians, with a prevalence of only 1 in 90 000 births. Sickle cell disease affects 1 in 400 to 600 African Americans, but it is rare among individuals of northern European descent. Tay–Sachs disease, a lethal recessive disorder seen in 1 in 3600 Ashkenazi Jewish births, is uncommon in most other populations.

Variation in the prevalence of genetic disease is but one aspect of human genetic variation. The evolutionary processes affecting "normal" human variation (e.g. traits such as height, skin color, blood groups, and DNA polymorphisms) also affect genetic disease variation. Four major evolutionary processes can be identified: mutation, natural selection, genetic drift, and gene flow. The relative contribution of each of these processes to genetic disease variation has been the subject of considerable controversy.

Much of this controversy arises from difficulties in specifying the precise nature of genetic variation. Until fairly recently, population variation in genetic disease was assessed primarily in terms of

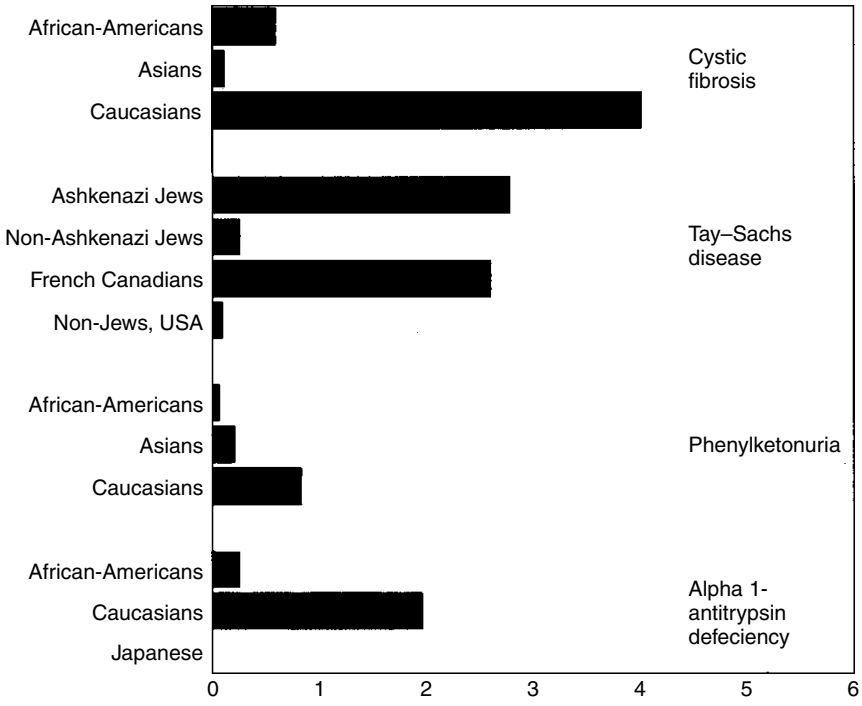

Fig. 1 Prevalence of selected genetic diseases (per 10 000 births) for a series of populations. Note that the French Canadian population refers only to those living in eastern Quebec.

protein variants. Protein electrophoresis could sometimes establish that different populations had different amino acid substitutions, leading to a disease (e.g. for sickle cell disease), but variation at the DNA level was largely unmeasurable. Furthermore, for most disease genes, the gene product, and thus the amino acid sequence, was unknown. Consequently, tracing the origins and evolution of genetic diseases in populations was often a highly speculative endeavor.

The molecular genetic techniques developed during the past two decades have improved this situation substantially. With millions of polymorphisms now identified in the human genome, it is feasible to examine polymorphisms near and within any disease locus. These polymorphisms, or markers, can take the form of restriction fragment length polymorphisms (RFLPs), short tandem repeat polymorphisms (STRPs), or single nucleotide polymorphisms (SNPs). It is becoming increasingly common to sequence entire genes or regions containing many genes in each study subject so that all variation in a region can be assessed. If several polymorphisms are measurable in the vicinity of the disease locus, haplotypes can be constructed for chromosomes carrying the disease mutation and for normal chromosomes. For example, a series of four two-allele SNPs, in which alleles are labeled 1 or 2, could form a haplotype composed of alleles 1, 2, 1, and 1 on the chromosomes bearing a particular disease mutation. Other haplotypes may be observed on normal chromosomes. Because recombination between closely linked polymorphisms is rare, these haplotypes can often be used to trace the evolutionary history of a disease mutation (i.e. under appropriate conditions, all affected individuals with the same chromosome haplotype should be descendants of the same individual). As will be shown in this article, comparisons of haplotypes in different populations can reveal whether a genetic disease had independent origins in each population.

As more and more disease genes are cloned, it is becoming possible to analyze not only marker haplotypes but also disease mutations themselves. This can be accomplished through techniques such as single-strand conformation polymorphism analysis (SSCP) or through direct DNA sequencing. Analysis of mutations sometimes reveals a tremendous diversity of different mutations at a single disease locus. Since the cloning of the CF gene (cystic fibrosis transmembrane conductance regulator, *CFTR*) in 1989, more than 1000 different mutations have been identified at this locus. As will be discussed below, these mutations vary in frequency from one population to another.

As a result of advances in molecular technology, our understanding of the role of evolutionary forces in creating and maintaining genetic variation among populations (including variation in genetic diseases) has increased considerably. This article will review the evolutionary mechanisms responsible for such variation, illustrating each mechanism with specific disease examples. It will also discuss the ways in which molecular genetic markers have contributed to our understanding of these mechanisms.

2 Mutation

Mutation, which is a heritable alteration in DNA sequence, is the ultimate source of genetic variation. While many mutations have no biological consequence for the

organism, some may produce changes in amino acid sequence that result in genetic disease. Mutations can occur as single-base substitutions (missense mutations that alter a single amino acid or nonsense mutations that produce a stop codon), deletions and duplications (some of which may produce frameshifts), alterations of splice sites (resulting in inappropriate inclusion of introns or exclusion of exons in the mature messenger RNA), promoter alterations (resulting in decreased transcription of messenger RNA), or insertions of mobile elements such as *Alu* or LINE1 repeats.

The average mutation rate in humans is approximately 10^{-9} per nucleotide per year. There is little evidence that mutation rates vary substantially among human populations. Thus, mutation itself does not account for much interpopulation variation in genetic disease. However, mutation rates do vary substantially from one disease gene to another and thus help explain why some diseases are relatively common and others are relatively rare.

2.1 Gene Size and Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is one of the more common lethal genetic diseases, affecting approximately 1 in 3500 males in most surveyed populations. Because it is an X-linked recessive disorder, it seldom affects females. Affected males usually die of cardiac or respiratory failure before age 20 and seldom reproduce. It is estimated that the DMD gene has one of the highest known mutation rates, approximately 10^{-4} (mutations per gene per generation). This high mutation rate helps to account for the fact that DMD is quite common in spite of its lethality in males.

Cloning the DMD gene has helped to explain why the mutation rate is so high. The DMD gene, which spans 2.3 million DNA bases and includes 14 000 bp (14 kilobases or kb) of coding DNA, is the largest gene known in the human. Its large size, quite simply, presents a large ''target'' for mutation. A similar example is given by neurofibromatosis type 1 (NF1), an autosomal dominant disorder that produces benign tumors associated with peripheral nerves. This disorder also has a high mutation rate, estimated as approximately 10^{-4}. The NF1 gene is again very large, spanning over 350 kb. The size of the coding DNA, 13 kb, is similar to that of the DMD gene. In general, mutation rate appears to correlate positively with gene size.

2.2 Mutation Hot Spots

A second factor influencing mutation rates involves DNA base-pair composition. It is known that the CG dinucleotide is highly susceptible to mutation. The cytosine base is usually methylated when it occurs next to a guanine, and methylated cytosine is likely to spontaneously lose an amino group. This produces a transition from cytosine to thymine. Surveys have shown that an inordinately large proportion of disease-causing mutations occur at CG dinucleotides. Thus, loci rich in such mutational ''hot spots'' are likely to have higher mutation rates. For example, achondroplasia, a reduced-stature condition, affects up to 1 in 15 000 live births, but the responsible gene (*FGFR3*, fibroblast growth factor receptor 3) spans 16.5 kb and is thus much smaller than the *NF1* or *DMD* genes. Remarkably, 99% of all mutations that cause achondroplasia occur at a single nucleotide (a methylated CG

hot spot) of *FGFR3*, where the mutation rate is several orders of magnitude higher than that of other nucleotides. Examples of other genetic diseases that have such mutational hot spots include phenylketonuria (PKU) and hemophilia A and B.

3 Natural Selection

Natural selection can be thought of as a screening process to which genetic variation is subjected. Advantageous variants are positively selected: individuals carrying the variants are more likely to survive and reproduce. This increases the frequency of the gene in the population. Disadvantageous variants will be selected against, reducing the frequency of the variant. For most genetic diseases, an equilibrium state will eventually be reached in which mutation introduces new copies of a disease-causing gene into the population while selection removes them at the same rate.

3.1 Heterozygote Advantage and Sickle Cell Disease

Certain recessive diseases present a slightly more complicated picture. In some cases, the homozygous recessive genotype may undergo negative selection, while the heterozygote may have a selective advantage. In this situation, the disease allele will be maintained at a higher frequency than if the heterozygote had no advantage. A good example of this is found in sickle cell disease. This autosomal recessive disorder, in which the erythrocytes assume a characteristic sickle shape and thus cannot move easily through the capillaries, is often fatal in homozygotes. The heterozygote has no health problems and, in a malarial environment, has a decided survival advantage. This is because sickle cell heterozygotes are resistant to infection by the *Plasmodium falciparum* malaria parasite. Consequently, heterozygotes have a survival advantage over both types of homozygotes. The frequency of the sickle cell gene is quite high in those parts of the world in which malaria has been endemic. It reaches its highest frequency in west-central Africa, where up to one in four individuals is a heterozygous carrier, and one in 45 is affected with the disorder. Sickle cell disease is also seen in parts of the Middle East, India, and the Mediterranean region. It is interesting that the frequency of the sickle cell mutation among African-Americans is substantially lower than in western Africa. This partly reflects admixture with Caucasians (see below), but it is likely also a result of a lack of natural selection in the malaria-free North American environment.

The best-studied of the sickle cell mutations is a single-base substitution (thymine instead of adenine) at the DNA triplet that specifies the sixth amino acid of the β-globin chain. This mutation results in a substitution of valine for glutamic acid known as the hemoglobin S (HbS) variant. At one time, it was thought that the presence of HbS in India and the Mideast was due to migration of Africans who carried the *HbS* gene. However, more recent investigations using RFLPs show that this is probably not the case. Marker haplotypes have been examined, using RFLPs in and around the β-globin locus. They show that the disease haplotypes occurring in Africa differ substantially from those occurring in the Mideast and India. Some haplotype variation can be expected as a result of gene conversion or recombination subsequent to the origin

of a mutation, but it is often possible to distinguish these events from multiple mutations. The RFLP haplotypes show that the HbS mutation arose at least twice, once in Africa and once in Saudi Arabia or India. Natural selection then operated in each environment independently to raise the frequency of the mutant gene. Molecular studies have shown that $\Psi\beta$, a pseudogene (i.e. a nontranscribed gene highly similar to β-globin in DNA sequence), does *not* increase in frequency among populations in malarial environments.

3.2 Natural Selection and HIV

Another example of natural selection came to light because of the human immunodeficiency virus (HIV). Some strains of this virus gain entry to macrophages and helper T cells via a cell-surface receptor that normally binds to a cytokine. The resulting viral destruction of helper T cells, a critical component of the body's immune system, leads to acquired immune deficiency syndrome (AIDS). Individuals who are homozygous for a 32-bp deletion of the gene that encodes one of the cytokine receptors (*CCR5*) lack the receptor on their cell surfaces and are thus remarkably resistant to HIV infection (because other cell-surface receptors can perform the same role as CCR5, the mutation has no ill effects). This deletion is especially common in northeastern European populations, where its frequency reaches 0.20. It is virtually absent in Asian and African populations. Analysis of haplotype variation in the chromosomal region that contains *CCR5* indicates that the deletion arose in European populations about 700 to 2000 years ago. Since HIV appeared in humans only a few decades ago, the high deletion frequency in northeastern Europe must be due to a selective force other than HIV or perhaps to genetic drift. Considering the age of the deletion, it was first suggested that it had conferred resistance against the bacterium, *Yersinia pestis*, that causes bubonic plague. However, recent research with mouse models demonstrated that *Y. pestis*' entry into cells is not affected by the absence of the CCR5 molecule. Other evidence suggests that the selective agent may instead have been the smallpox virus.

4 Genetic Drift and Founder Effect

Often, small, isolated populations exhibit high frequencies of genetic diseases that are rare in other populations. For example, Ellis van Creveld syndrome, a very rare disorder that involves reduced stature, is seen with increased frequency among the genetically isolated Old Order Amish population of Lancaster County, Pennsylvania. In fact, nearly as many cases have been observed in a single Amish kindred as have been observed in the rest of the world. In the Finnish population, which has also been quite isolated until recently, over two dozen otherwise rare autosomal recessive diseases occur with substantially elevated frequencies. Such variation in disease prevalence is usually the result of the related processes of genetic drift and founder effect.

Genetic drift refers to the random fluctuation in gene frequencies that occurs from one generation to the next as a result of sampling a limited number of gametes. In small populations, the degree of fluctuation in gene frequency increases (just as a coin-tossing experiment using only 10 coins is quite likely to result in a large deviation from the expected proportion of

50% heads and 50% tails). Genetic drift can thus lead to high frequencies of genetic diseases in small populations. Founder effect occurs when a small number of individuals form a new population. Because these individuals form a small sample of an original population, their genes are unlikely to form a representative sample of the original population from which they came. This can again result in a highly skewed distribution of disease genes among their descendants. The Old Order Amish population, for example, was founded by only about 50 couples. This effect is further exaggerated when certain founders have a disproportionately large number of descendants.

Traditionally, demographic history and genealogies have been used to demonstrate drift and founder effect. Genealogical analysis demonstrated, for example, that all 30 000 cases of porphyria variegata in the South African Afrikaner population could be traced to a single couple who emigrated from Holland in the 1680s. This approach is obviously limited by the availability of extensive genealogies.

4.1 Haplotype Analysis

More recently, molecular genetic markers have made it possible to assess founder effect at the DNA level. Haplotype analysis is particularly helpful in this regard. It is reasonable to assume that each different haplotype background associated with a disease represents a different founder. Thus, the number of distinct disease haplotypes can be counted to infer the number of founders who introduced a disease into a population. In northern Finland, it was shown that all individuals affected with X-linked choroideremia, a disease that causes blindness, had the same RFLP haplotype (using markers closely linked to the choroideremia gene). This provided evidence that each of these individuals was descended from the same common ancestor. Genealogical analysis proved this to be the case: all affected individuals shared a common ancestor that lived 12 generations ago. A similar exercise showed that the high frequency of PKU among Yemeni Jews can be attributed to the descendants of a single founding couple who lived in the seventeenth century. Haplotype analysis of markers closely linked to the *CFTR* locus demonstrated that all studied cases of CF in the Hutterite population could be traced to three founders.

The disease consequences of founder effect and genetic drift have been especially well characterized in the Ashkenazi Jewish population. For example, torsion dystonia, a rare recessive disorder, has an elevated frequency in this population. Analysis of haplotype variation has shown that the disease-causing mutation is only about 350 years old and has likely been amplified in frequency because of population bottlenecks and subsequent expansion. Similarly, three mutations in the *BRCA1* and *BRCA2* genes have reached a combined frequency of 2.5% in Ashkenazi Jews and account for a substantial proportion of inherited breast cancer cases. A mutation in the *APC* gene is found in about 1/20 members of this population and confers a twofold increased risk of developing colon cancer. This mutation alone accounts for about 10% of colon cancer cases in the Ashkenazi population.

4.2 Mutation Analysis

The cloning of disease genes often permits direct analysis of population variation

in mutations. One of the best examples is the ΔF508 (deletion of a phenylalanine residue at position 508) mutation in the *CFTR* locus, a three-base deletion that produces a loss of function and accounts for approximately 70% of the *CFTR* mutations found in Caucasians. Extensive population analysis has shown that the proportion of *CFTR* mutations accounted for by ΔF508 has a north–south cline, with a maximum of about 70 to 90% in northern Europe (where the disease itself is most common) and a minimum of about 50% in southern Europe. The proportion of ΔF508 mutations is even lower among other surveyed populations, such as African-Americans (37%) and Ashkenazi Jews (30%). The elevated frequency of CF among Europeans can be traced primarily to the ΔF508 mutation, since the frequencies of non-ΔF508 mutations are quite similar among Europeans, Asians, and Africans. Among Europeans, the great majority (>90%) of ΔF508 mutations occur on a single haplotype background, indicating that most current copies of the mutation may have descended from the same common ancestor.

Cloning of the *CFTR* gene has helped explain why CF has a high frequency in European populations. *CFTR* encodes a chloride channel found on the surfaces of epithelial cells that line the gut and the airway. The number of chloride channels in these cells is substantially reduced in transgenic mice that carry one copy of the ΔF508 mutation. The bacterium that causes typhoid fever, *Salmonella typhi*, gains access to intestinal cells via these chloride channels, and, as predicted, heterozygous mice are quite resistant to typhoid fever infection. It is reasonable to conclude that humans who were heterozygous for this mutation also benefited from resistance to typhoid fever.

5
Drift or Selection?

When a genetic disease is seen with high frequency in a population, it is often unclear whether it is caused by a selective advantage or genetic drift/founder effect. In a few cases (such as sickle cell disease or CF), a demonstrable selective agent is known. But in most cases, the evidence is far more equivocal. Here again, molecular markers have been helpful.

5.1
Hemochromatosis in Europe

Idiopathic hemochromatosis is an autosomal recessive disorder in which excess iron is absorbed in the gut and deposited in many parts of the body, including the skin, joints, liver, pancreas, and heart. Consequently, some homozygotes develop liver disease, heart failure, arthropathy, diabetes, and other disease-related conditions late in life. Approximately 1 in 300 Europeans is homozygous for mutations in the responsible gene, *HFE*. Although several different *HFE* mutations have been reported, 85% of them consist of a cysteine→tyrosine substitution that results in a loss of function of the *HFE* product. Haplotype analysis has shown that this mutation has occurred only once and is confined almost exclusively to the European population. Analysis of variation in markers near *HFE* has shown that the primary disease-causing mutation took place only about 60 to 70 generations ago. The mutation could have achieved a high frequency in this population either through drift or natural selection, but extensive analysis of marker variation near the *HFE* gene has shown that

it is extremely improbable that drift alone could have elevated the mutation frequency so quickly. In addition, population surveys show that heterozygotes have a significant reduction in the frequency of iron-deficiency anemia. Thus, a heterozygote advantage is likely to account for a rapid increase in the frequency of this mutation.

5.2
G6PD Deficiency in Africa and the Mediterranean

G6PD (glucose-6-phosphate-dehydrogenase) deficiency is in X-linked disorder that affects 400 million individuals worldwide and can result in hemopathology when mutation carriers are exposed to specific infections, drugs (e.g. primaquine), or foods (e.g. fava beans). G6PD deficiency, like sickle cell disease, confers resistance to infection by the malaria parasite, *P. falciparum*. Molecular analysis has shown that a major mutation, A-, is common in Africa, while another major mutation, Med, is common in Mideastern and Mediterranean populations. The A-mutation occurred approximately 6000 years ago, and the Med mutation occurred approximately 3000 years ago. The recent ages of these mutations reflect limited haplotype diversity and indicate that genetic drift alone could not have elevated these mutations to high frequency in just a few thousand years. Natural selection, as a result of malarial resistance, must have played an important role in raising the frequencies of these mutations. It is interesting that the form of *P. falciparum* responsible for severe malaria probably did not arise until about 10 000 years ago, after the introduction of agriculture in these areas.

6
Gene Flow

Gene flow reduces genetic differences among populations. When two populations both manifest a genetic disease, the question often arises whether the disease mutation arose independently in the two populations or was communicated from one to another via gene flow. When only a disease phenotype can be observed, it is difficult to answer this question. However, more precise molecular characterization of disease loci often illuminates the issue.

6.1
Cystic Fibrosis in African-Americans

An example is given by CF in the African-American population. This disease affects approximately 1 in 17 000 African-Americans, a prevalence much lower than that of Europeans. One hypothesis is that the disorder was introduced into the African-American population through gene flow from the European-American population. However, analysis of CF mutations shows that ΔF508 is quite rare among African-Americans and that two-thirds of the observed CF mutations are unique to this population. Thus, CF almost certainly had independent origins in the African-American population and is not principally derived from European-Americans.

6.2
Tay–Sachs Disease in French Canadians

Studies of Tay–Sachs disease in Quebec provide another example. As one would expect, the Ashkenazi Jewish population of this region has an elevated prevalence of this disorder, and the frequencies of

the two major mutations closely match those of other Ashkenazi Jewish populations. Tay–Sachs disease is also seen among the French Canadian population of Quebec. In fact, in the eastern portion of the province, the disease gene frequency is as high as among Ashkenazi Jews. Does this reflect gene flow from the Jewish population, or was there an independent origin? Direct examination of the Tay–Sachs gene shows that the French Canadians usually carry a 7.6-kb deletion that is not found among Jews. Thus, an independent origin is established. Further investigations may ultimately establish whether the high frequency of the disorder among French Canadians is the result of founder effect or natural selection.

7 Genetic Variation and Common Diseases

The examples used thus far have all involved relatively rare single-gene diseases. In each case, mutations have increased in frequency as a result of factors such as drift or selection. Increasing attention is now being devoted to mutations responsible for common diseases such as diabetes, heart disease, and common cancers. The most significant of these mutations are those that have reached high frequency (e.g. >10%). Typically, such mutations are relatively old and are thus shared among most worldwide populations. Their frequencies vary among populations, however. For example, the Є4 allele of the apolipoprotein E (*APOE*) gene, which confers an increased risk of developing Alzheimer's disease, exhibits frequencies above 30% among some African populations (e.g. Pygmies, Khoi San, Sudanese, and Nigerians) but substantially lower (<15%) among southern Europeans and Asians (there is also evidence, however, that the association between Є4 and Alzheimer's disease is weaker among individuals of African descent than among those of European descent). A gain-of-function mutation in the *SCN5A* gene, which encodes a sodium channel present in cardiac myocytes, confers an eightfold increased risk of cardiac arrhythmia and was found in approximately 13% of African-Americans but was absent in samples of 511 Europeans and 578 Asians. A promoter variant of the angiotensinogen (*AGT*) gene is associated with an increased risk of hypertension and reaches high frequencies in African populations. Haplotype analysis has demonstrated that natural selection has acted to decrease the frequency of this variant in non-African populations, possibly as a result of their adaptation to nontropical, high-sodium environments after they left the African continent. Differences in the frequencies of mutations such as these may help account for differences in the prevalence of common diseases in populations, although environmental factors such as diet must also have important effects. It is critical to point out that, because of the recent origin of modern humans from a small founder population and continued gene flow among populations through time, most of these variants tend to be shared among major populations and typically vary only in their frequencies.

8 Perspectives

This review has highlighted some ways in which the study of disease variation in populations can be related to evolutionary processes. Such studies are significant

in understanding evolutionary biology. They have other implications as well. An awareness of population variation in disease can aid in clinical diagnosis. For example, a physician evaluating a child who presents with recurrent respiratory infections and failure to thrive should include ethnic background in considering a differential diagnosis. If the patient is of African descent, sickle cell disease is a distinct possibility. If the patient is of northern European descent, sickle cell disease would be unlikely (but not impossible), whereas cystic fibrosis should be considered. In some cases, knowledge of the potential adaptive significance of a genetic disease (e.g. the heterozygote advantage for sickle cell disease, cystic fibrosis, or hemochromatosis) may lead to increased understanding of gene function and pathophysiology.

When considering genetic variants that contribute to common diseases, as well as those that influence response to therapeutic drugs, it should be emphasized that most such variants are shared among most major human populations, varying only in their frequencies. Consequently, population affiliation (or ''race'') is, at best, a very approximate indicator of critical factors such as drug response.

Advances in molecular genetics have greatly improved our understanding of the evolutionary processes leading to population variation in genetic disease. Yet many important questions remain unanswered, particularly for common, complex diseases. As more polymorphic markers are analyzed, more DNA sequenced, and more disease genes cloned, new and more profound insights are certain to be gained.

Keywords

B cells
Lymphocytes generated in the bone marrow that secrete antibodies after activation.

T cells
Lymphocytes generated in the bone marrow and educated in the thymus to recognize peptides presented by major histocompatibility antigens.

T helper cells (Th cells)
A subset of T cells orchestrating the immune response and helping B cells to produce antibodies.

Th1 cells
A subset of Th cells, characterized by the production of IFNγ and driving effector responses against intracellular pathogens, bacteria, and fungi.

Th2 cells
A subset of Th cells, characterized by the production of IL-4, IL-5, and IL-13, driving effector responses against multicellular parasites.

Cytotoxic T cells (CTLs)
A subset of T cells killing infected host cells and tumor cells.

Dendritic cells (DCs)
The most potent antigen-presenting cells. Essential for the induction of T-cell responses.

Many cell types make up the arsenal of the immune system and are directly involved in the destruction of invading pathogens. Broadly, two types of cells can be distinguished: firstly, some cells recognize signals that are associated with pathogens, such as tissue damage or patterns found on pathogens but not in the host. These cells belong to the innate immune system and appeared first during evolution. The second type of cells, the lymphocyte, has developed a complex machinery that allows each lymphocyte to express a single and unique receptor with random specificity,

the B- and T-cell receptors. Once these receptors recognize a pathogen, the lymphocyte encoding the receptor undergoes clonal expansion and the lymphocyte population differentiates into effector cells, ridding the pathogen. Lymphocytes therefore make up the specific or adaptive immune system. This article discusses how the various cell types protect from infection with pathogens and elucidates some of the complex interactions between the two systems.

1 Introduction

Metazoan organisms have evolved defense systems to a level of near perfection, such that severe or sustained infections are rare. The immune system is divided into an innate system and an adaptive system. The innate immune system acts rapidly and is the most important part of immune defense, as most organisms are able to survive through innate immune mechanisms alone. Only vertebrates have evolved additional mechanisms for pathogen recognition and elimination, so-called *adaptive immunity*.

The innate immune system involves a broad array of different cell types, as many cells and organs of the host have evolved to defend themselves against microbes. For decades, the innate immune system has been regarded as somewhat ''unspecific'' or even ''primitive.'' However, in recent years it has become more and more apparent that the strategy of the innate immune system is to detect molecules that are common and conserved in a broad range of microorganisms and that are different from molecules of the host itself. It has been discovered that the innate immune system recognizes certain molecular patterns that are present in microbes but not in the host, so-called *pathogen-associated microbial patterns* (PAMPs). The receptors recognizing those microbial patterns are called *pattern recognition receptors* (PRRs). Many cell types of the innate immune system express PRRs, so that the innate immune system can react very rapidly.

In contrast to the innate immune system that has certain specificity for microbes, late evolution in vertebrates has developed an even more specific and more complex system of so-called *adaptive immunity*. The adaptive immune system is able to specifically recognize any protein (or even sequences thereof) that is not normally present in the host, and thus represents an invader. The key players in mounting an adaptive immune response are dendritic cells that induce T- and B-cell responses. The adaptive immune system's high specificity has the disadvantage that early in an infection, only few T and B cells that can recognize the microbe are present and these few specific T and B cells first have to proliferate to an ''army of relevant size.'' This proliferation takes several days during which the innate immune system is the one fighting the microbes. Also, the innate immune system produces an array of different signals in the form of cytokines and chemokines as well as cognate interactions to support the adaptive immune system. Thus, the battle of the innate immune system against a microbe may be interpreted as a ''wake-up call'' to the adaptive immune system. Once an adaptive immune response has been generated, which includes a microbe

specific antibody- and T-cell response, the adaptive immune system also supports the innate immune system, for example, by coating microbes with antibodies so that they can be better phagocytosed (so-called *opsonization*), or by providing T-cell dependent cytokines that enhance the phagocytic activity of the innate immune cells.

Only very few of the microorganisms present in the environment pass all the lines of defense in a vertebrate host. Already in order to pass the first barrier, that is, chemical and physical barriers such as mucus, saliva, cilia movements, and epithelia with tight junctions, specialized pathogen receptors are required for pathogen adherence and penetration. Even fewer microorganisms will pass the innate immune system that has cells positioned in close association with the skin and mucosal surfaces, which are the usual sites of microbe entry. Microbes that have been eliminated either by physical or chemical barriers or by the innate immune system do not usually cause clinically manifest disease. Only those microbes that have passed all these lines of defense are dangerous for the host and will elicit a specific immune response and should actually be called *pathogens*. The adaptive immune response, in concert with an enhanced innate immune response, finally eliminates the pathogen. The immune

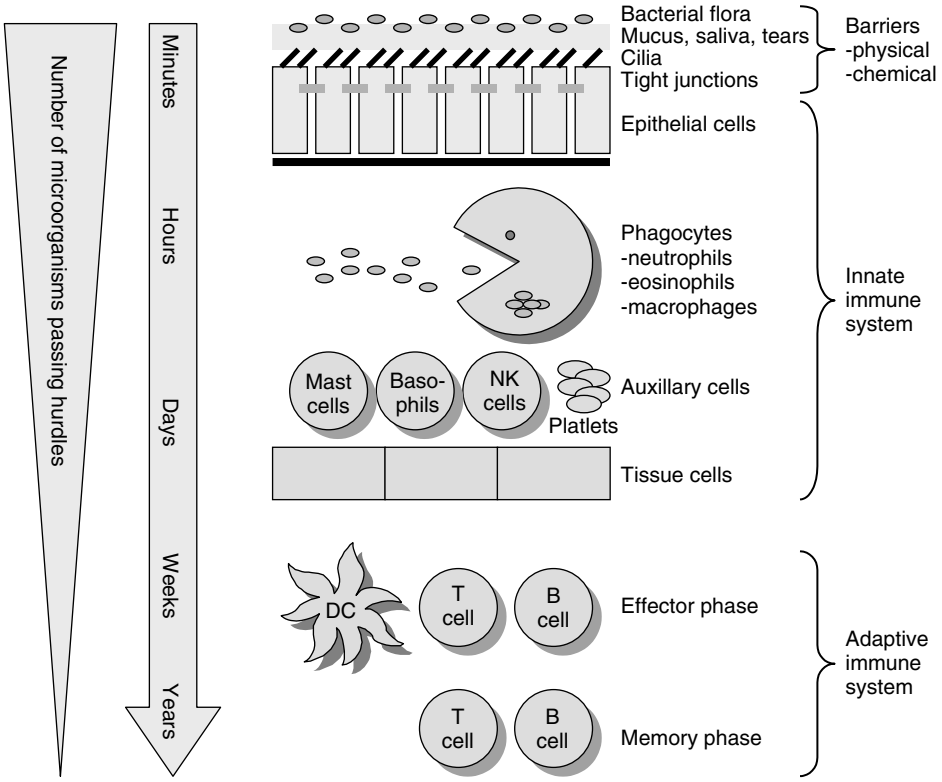

Fig. 1 Cells of the innate and adaptive immune response. Number of microorganisms that pass lines of defense and induce a response, as well as approximate time for response.

system thereafter tries to keep these dangerous microbes in mind by generating an immunological memory. Even here there are different levels of immunological memory that again depend on the virulence and persistence of the pathogen. Against persisting pathogens, for example, tuberculosis or other pathogens inducing granulomas, immunological memory is strong with pathogen-specific T cells constantly activated and alert. In addition, B cells are repeatedly restimulated to produce high and persistent levels of antibody. In contrast, if the pathogen does not persist, the immune system keeps the pathogen-specific B- and, in particular, T cells at a functionally lower level.

Figure 1 summarizes the three major lines of defense, that is, physical and chemical barriers, followed by the innate immune system consisting of phagocytes, auxiliary cells, and tissue cells. Only very few pathogens pass these first lines of defense so that an adaptive immune response is generated. An arrow indicates the approximate time frames it takes for the immune system to react.

2 Innate Immunity

2.1 Epithelial Cells

Epithelial cells have a variety of immunological functions. Most microorganisms that an individual encounters do not penetrate the body surface, but are prevented from entering by external or internal epithelial surfaces. Epithelial cells are joined by tight junctions that form an effective seal against the outside environment. Moreover, the epithelial lining of the respiratory tract is covered by sticky mucus. Possible invaders are trapped in the mucus and are then transported outward by moving cilia on the respiratory epithelium.

In addition to these mechanical defense mechanisms, the skin and mucosa also produce antimicrobial chemical substances that cover their surfaces. Tears and saliva contain the antimicrobial enzyme lysozyme. Epithelial cells also release low-molecular-weight antimicrobial peptides. The best characterized peptides belong to the family of so-called *defensins*, which have molecular masses between 3 to 6 kD and have the physicochemical properties to insert into membranes and disrupt their structure. Defensins are subdivided into two structural classes, alpha (α) and beta (β). So far, six α-defensins and three β-defensins have been described in humans. The α-defensins are produced primarily by intestinal Paneth cells, whereas airway epithelial cells produce mostly β-defensins. Defensins have a broad-spectrum antimicrobial activity ranging from gram-negative to gram-positive bacteria, as well as some viruses and fungi. The digestive tract produces antimicrobially active acid, digestive enzymes, and α-defensins. The lungs produce surfactant proteins A and D that coat the pathogen surface and enhance phagocytosis by macrophages. Last but not least, most epithelia are covered with a flora of nonpathogenic bacteria that compete with pathogenic bacteria for nutrients and can also produce additional antibacterial peptides and other substances.

Apart from the above-mentioned direct antimicrobial activity, epithelial cells are important regulators of the immune response. Epithelial cells produce numerous cytokines, cytokine antagonists, chemokines, colony-stimulating factors, and growth factors that all have the capacity to recruit multiple inflammatory cells.

Epithelial cells of mucosal surfaces also contribute to mucosal immunity through secretion of IgA. The basal epithelial cell surface expresses the secretory component, acting as a specific receptor for IgA dimers. This complex is then transported and secreted through the apical surface. Such secretory IgA contributes to antiviral and antibacterial immunity.

Epithelial cells can further internalize antigen and express major histocompatibility complex (MHC) class I and class II molecules. Epithelial cells also express costimulatory molecules, such as CD80 and CD86, which are essential for activating T cells. Thus, epithelial cells may be able to recruit inflammatory cells and sustain a local T-cell response through antigen presentation and costimulation.

2.2 Neutrophils

Neutrophils constitute the majority of the blood leukocytes. They develop in the bone marrow from the same precursors as monocytes and macrophages. After release from the bone marrow, mature neutrophils have a short transit time of only 6 to 8 h in the circulation. Then, neutrophils are stored in tissue sites through so-called *margination*. This mechanism guarantees that upon infection, a large pool of mature neutrophils is rapidly available. Because neutrophils are present in larger numbers than any other inflammatory cell in the circulation, they are the most important cells in initiating the acute tissue response to injury and infection.

In order to enter the tissue, neutrophils must adhere to the endothelium and migrate through the blood vessel, a process that is regulated by cell adhesion molecules (CAMs). These CAMs are present on neutrophils and endothelial cells where they are upregulated at sites of inflammation. Apart from CAMs, neutrophil migration also requires chemotactic mediators. Neutrophil chemotactic mediators include chemokines, most importantly Interleukin-8 (IL-8), bacterial products, complement split products, as well as leukotrienes, and other lipid mediators.

Classically, neutrophils are regarded as phagocytes. Indeed, neutrophils are highly efficient at taking up and digesting bacteria and other pathogens. Since neutrophils express a variety of receptors for the constant part of antibodies (Fc), they are most potent at eliminating antibody-decorated pathogens. Moreover, neutrophils have recently been reported to function as scavenger cells, which deliver antigens, in particular bacteria, into the spleen for induction of an adaptive immune response. However, neutrophils are far more than that and produce antimicrobial agents such as proteases, oxygen radicals, and defensins upon activation, as well as lipid mediators that lead to further cellular recruitment.

A variety of highly active substances are stored preformed in the granules of granulocytes. The serine proteinases neutrophil elastase, cathepsin G, and proteinase-3 are ''ready-to-use'' stored in the azurophilic granules of mature neutrophils. From there, they can either be transferred to the phagolysosomes or are released upon stimulation. Once released, neutrophil serine proteinases digest a number of extracellular matrix proteins, including elastin, collagen (types I to IV), fibronectin, laminin, and proteoglycans, which may lead to extensive tissue damage.

Release of oxygen radicals from neutrophils or other inflammatory cells apparently plays an important role in causing tissue damage at sites of inflammation.

Among the lipid mediators released by activated neutrophils are leukotrienes (LTB_4) and platelet-activating factor (PAF). Both cause further neutrophil migration and activation, thus amplifying the neutrophil inflammatory response.

Human neutrophil defensins, or human neutrophil peptides (HNP-1 to HNP-4) are small (relative molecular mass 3.54 kD) cationic peptides defined by their antimicrobial activity, but may, however, have further immunoregulatory functions.

2.3 Monocytes and Macrophages

Monocytic cells are released from the bone marrow and reach the blood as monocytes. From there, monocytes leave the circulation to reach their resident site in tissues where they differentiate to so-called *macrophages*. Macrophages are recruited to foci of inflammation.

Monocytes and macrophages play a critical role in host defense, not only in innate immunity but also in regulation of the subsequent adaptive immune response. Monocytes and macrophages produce an array of inflammatory mediators and cytokines, such as IL-1β, TNF-α, GM-CSF, IFN-γ, IL-8, iNOS, RANTES and also lipid mediators such as leukotrienes (LTC_4) and prostaglandins (PGE_2). Their function is mostly proinflammatory; under certain circumstances, monocytes and macrophages can, however, also suppress an immune response by producing IL-10.

Macrophages and monocytes are also important in adaptive immunity, as they express receptors for immunoglobulins G and E (IgG, IgE). Also, T cells and NK cells activate the phagocytic and microbicidal function of macrophages and monocytes by interferon gamma (IFN-γ). IFN-γ enhances the capacity of monocytes and macrophages to present antigen, including the upregulation of MHC class I and II molecules.

2.4 Natural Killer Cells

Natural killer (NK) cells are bone marrow-derived lymphocytes. They comprise the third major lymphocyte population and can be distinguished from other lymphocytes by the absence of B- and T-cell antigen receptors, that is, sIg and T-cell receptor (TCR) respectively. NK cells are capable of lysing certain tumor cells without prior sensitization. Because of this capacity, termed *natural killing*, NK cells were initially thought to serve primarily in defense against tumor cells. Over the years, however, NK cells have been shown to have additional functions. They produce cytokines that regulate the development of acquired, specific immunity, and are involved in the regulation of Th1 versus Th2 development.

NK cells provide early defense against pathogenic organisms during the initial response period against a variety of microorganisms, most importantly against viruses, but also against bacteria and protozoa. NK cells recognize their targets via two general types of receptors. NK cells express inhibitory receptors specific for MHC class I molecules on target cells. This inhibitory receptor prevents the NK cell from activation and killing healthy tissues of the host (''missing-self'' hypothesis). NK cells also express activation receptors that recognize target cell ligands and can trigger perforin-dependent natural killing. Many of these activating receptors, such as Ly49D and Ly49H, are structurally related to the inhibitory receptors. The two

types of receptors, inhibitory and activating, cross-regulate each other and the balanced signal of the two will determine NK cell activation. Stimulation of NK cells through the activation receptors can lead to production of proinflammatory cytokines such as IFNγ, TNF-α, and granulocyte-macrophage colony-stimulating factor (GM-CSF).

NK cells are also activated by cytokine stimulation. Infected or activated dendritic cells (DCs) and macrophages produce cytokines and chemokines such as IFNα/β, IL-12, IL-15, and IL-18 that stimulate NK cells to rapidly produce other cytokines (including IFNγ, TNFα, and GM-CSF) and chemokines (such as ATAC/lymphotactin, Mig, and MIP-1α), resulting in further activation of immune cells.

2.5 Eosinophil Granulocytes

Eosinophils derive from the bone marrow. They are considered to merely pass through the blood circulation to finally reside in the tissues. The ratio of tissue eosinophils to blood is around 100 : 1. The highest density of eosinophils is found in mucosal tissues, a localization pattern that attests to their role in the mucosal immune response.

Eosinophils possess an arsenal of numerous highly basic and cytotoxic granule proteins, as well as enzymes designed to inflict oxidative damage on biologic targets. This weaponry is released on eosinophil activation.

The eosinophil contains an array of cytotoxic granule proteins. Major Basic Protein-2 (MBP-2) is a potent cytotoxin and helminthotoxin. It is also bactericidal, and virucidal. Eosinophil Cationic Protein (ECP) is a highly potent toxin for parasites. Eosinophil-Derived Neurotoxin (EDN) is a potent neurotoxin. Eosinophil peroxidase (EPO) in the presence of H_2O_2 kills microorganisms and tumor cells. A variety of other enzymes are also found in the eosinophil, including Arylsulfatase B and lysozyme.

Apart from a direct cytotoxic and antimicrobial function, the eosinophil also acts as a regulator of the immune response. It contains lipid bodies that serve as a storage site for the production of lipid mediators, predominantly leukotriene C_4 (LTC_4). Eosinophils are also sources of growth factors as well as regulatory or proinflammatory cytokines and chemokines, such as IL-3, IL-4, IL-5, IL-8, IL-16, GM-CSF, TGF-α, TGF-β_1, RANTES, PAF, TNF-α, and MIP-1α.

Eosinophils express various membrane receptors that regulate their trafficking and activation, including adhesion receptors, receptors for the constant portion of immunoglobulins (Fc), as well as receptors for cytokines and lipid mediators.

The major role of eosinophils appears to lie in defense against large organisms, such as multicellular parasites, which are too large for phagocytosis. Eosinophils may respond to carbohydrate ligands on the parasite surface, such as the $Lewis^X$-related molecules, and cell adhesion molecules that appear similar to selectins. Interestingly, eosinophil action in the lung is under the control of Th cells. Specifically, while eosinophils may be recruited to the lung during an allergic reaction in a Th cell independent fashion, the presence of Th cells in the lung is required for the degranulation of eosinophils. This is yet another example of the complexity of the interaction between cells of the innate and adaptive immune system and how the systems

cross-regulate each other in order to focus the responses on potentially dangerous pathogens.

2.6 Basophils and Mast Cells

Basophils account for less than 0.2% of all leukocytes. The granules in basophiles contain an abundance of mediators, the most important ones being histamine, heparin, and leukotrienes. Upon cross-linking of the high affinity IgE receptor (FcεRI), basophils degranulate and can cause severe systemic symptoms of allergy including anaphylactic shock. However, basophils also play a role in the immune response against parasites by augmenting inflammation.

Mature human mast cells are rounded or spider-like cells of 9 to 12-µm diameter, which contain a striking amount of granules that, when stained, behave metachromatically. Mast cells are present in nearly every organ tissue, but high numbers of mast cells are found in potential entry ports for pathogens, such as the skin, and the mucosal surfaces of the eye, the gastrointestinal tract, and the respiratory tract.

Two types of mast cells, differing in their granule contents and in their patterns of mast cell–specific proteases can be distinguished. Human mast cell nomenclature is based on neutral protease composition. Whereas MC_T cells express tryptase alone, MC_{TC} cells produce tryptase, chymase, mast cell carboxypeptidase, and cathepsin G. It can be said that MC_T cells predominate in the normal lung, particularly in the alveoli, and in the small intestine mucosa. MC_{TC} cells are the predominant type found in normal skin, blood vessels, gastrointestinal submucosa, and synovium.

Mast cells are well-known effectors of allergic disease, as they express the high-affinity receptor for immunoglobulin E (IgE). If cross-linked by an allergen, the mast cell immediately degranulates an array of mediators, one of the most rapidly acting being histamine.

While it is clear that mast cells are responsible for making patients suffer from their allergies against harmless substances such as pollen or food, it is extremely difficult to find a positive role for mast cells. It is not until recently that a new and positive role of the mast cell in protective immunity against parasites and bacteria is emerging. Animal studies with parasites showed a correlation of mast cell numbers with parasite expulsion that can be readily attributed to mast cell mediators such as histamine, proteases, and cytokines. The immune response initiated by mast cell-released mediators also involves eosinophils, and Th2 cells. More recent animal studies using mast cell-deficient mice, however, suggest that it is not the mast cells themselves, but the Th2 type immune response that is the key to antiparasite immunity. Interestingly, mast cell–deficient mice also appear more susceptible to bacterial infections, suggesting a role for the mast cell in innate immunity. Mast cells produce tumor necrosis factor alpha (TNF-α), a strong chemo attractant for neutrophils, offering an explanation for the antibacterial activity of mast cells.

2.7 Tissue Cells

Although usually not regarded as part of the immune system, tissue cells possess antimicrobial defense mechanisms that are the key to host survival. Here, interferons must be mentioned. Host

cells, upon viral infection, start producing IFN-α and IFN-β. These interferons induce resistance to viral replication in neighboring uninfected cells. Interferons also upregulate class I MHC molecules, thus making virally infected cells more susceptible to CD8+ T cell-mediated killing, so that the virus is more rapidly eliminated. Finally, interferons activate NK cells, which then kill virus-infected cells.

2.8 Platelets

In addition to their role in blood clotting, platelets are involved in inflammation. Each day an adult human produces 10^{11} platelets that are split off from megakaryocytic cells in the bone marrow. Injury to endothelial cells induces platelet adherence and aggregation, leading to platelet activation and degranulation. Platelet granula contain serotonin so that capillary permeability is increased, as well as fibrinogen that activates complement and attracts leukocytes. Interestingly, platelets express CD40 ligand, a molecule critical for activation of B cells, macrophages, and dendritic cells, suggesting a possible role of platelets in the regulation of innate and adaptive immune responses.

3 Adaptive Immunity

3.1 Cell Mediated versus Antibody Mediated Immunity

The adaptive immune system is based on two pillars, T cells and B cells. T cells are responsible for cell-mediated immunity while B cells produce antibodies, the basis of humoral immunity. Although the two arms are intimately linked with T cells regulating B-cell responses (in particular, through T help) and vice versa, B cells influencing T-cell responses, the basic functions and tasks of B and T cells are quite distinct (Table 1). Antibodies are important for protection against a variety of pathogens, in particular, many viruses and bacteria. Although antibodies are essential for protection against most secondary infections, they also play a major role during many primary infections and absence of antibodies results in increased susceptibility to many viruses, such as rotaviruses and polio virus. T cells also play a major role during many primary viral infections. Cytotoxic T cells (CTLs) are the key to the elimination of many non- or poorly cytopathic viruses, such as hepatitis B and C. CTLs also play a major role in keeping persistent infections under control. Th cells, on the other hand, play a

Tab. 1 Effector mechanisms for the elimination of pathogens and tumors.

Type of disease	*Dominant effector mechanism*	*Example*
Primary infection	Antibody, T cell, innate	Rota virus (Ab), hepatitis B (T cell), Streptococcus (innate)
Secondary infection	Antibody	Rota virus, polio, hepatitis B
Chronic infection	T cells	HIV, HCV
Solid tumor	T cells	Melanoma
Single-cell tumors	Antibody (monoclonal)	B-cell lymphoma

more complex role. Th cells are critical for the B-cell response, which remains abortive in the absence of Th. This not only helps in eliminating pathogens in acute infections but may also be essential in preventing the loss of CTL-memory during chronic infection. In addition, Th cells act more directly on CTLs by facilitating the induction of proliferation competent memory CTLs (see Sect. 4).

The situation for cancer appears different since antibodies play a minor role in control of tumor growth. As antibodies do not efficiently penetrate tissues, their ability to kill tumor cells remains limited. The monoclonal antibody herceptin, which is directed against breast cancer cells, and has proven successful in patients, is probably a rather exceptional case. Another exception is single-cell tumors, such as lymphomas, as they are more accessible to antibodies than solid tumors. This is well documented by the clinical efficacy of a variety of monoclonal antibodies, such as anti-CD20 antibodies (Rituximab), which eliminate B cells in an Fc receptor dependent fashion. Yet, the importance of naturally induced lymphoma specific antibodies remains to be documented. In addition to a possible direct antitumor activity, antibodies may facilitate presentation of tumor-associated antigens by DCs and other antigen-presenting cells (APCs), leading to heightened T-cell responses. It is this T-cell response that appears most apt to reduce tumor burden, since T cells have the ability to enter solid tumor tissues. The key antitumor effector cells are CTLs, which can induce direct lysis of tumor cells. In addition, Th cells locally produce cytokines in the tumor mass, creating a proinflammatory milieu, facilitating elimination of tumor cells by recruitment and activation CTLs and nonspecific cells such as macrophages or eosinophils.

3.2 Induction of Cell-mediated Immunity: T-Cell Activation

T-cell activation is a carefully orchestrated process optimally driven by professional antigen-presenting cells, such as DCs, which express high levels of accessory and costimulatory molecules. Several additional parameters regulate T-cell activation, including the kinetics and duration of antigen presentation as well as the activation status of DCs. The following sections will discuss these parameters in more detail.

3.2.1 Costimulation

Antigen-specific stimulation of T cells through the TCR alone is not usually sufficient for full T-cell activation. On the contrary, T-cell responses remain abortive in the absence of costimulation by accessory molecules, resulting in T-cell tolerance or anergy, rather than activation. T-cell anergy characterizes nonfunctional T cells that fail to proliferate upon exposure to antigen and therefore are not able to mediate an effective immune response. The most prominent costimulatory molecule on T cells is CD28, a receptor triggered by the B-7 family members CD80 and CD86 expressed on professional antigen-presenting cells, in particular dendritic cells. Indeed, engaging CD28 together with the TCR results in a reduced number of TCRs that need to be triggered for T-cell activation and enhances TCR-mediated signal transduction. Moreover, CD28 delivers an additional, poorly understood, signal into T cells, preventing induction of T-cell anergy. Yet, many viruses and other pathogens are able to induce strong and protective T-cell responses in the absence of CD28.

This may not reflect truly costimulation-independent T-cell activation but may rather be explained by the usage of alternative costimulatory molecules, such as ICOS. Indeed, ICOS has been shown to be responsible for CD28-independent activation of T-cell responses upon infection with vesicular stomatitis virus (VSV). OX40 and 41BB, members of the TNF-receptor family are additional molecules involved in T-cell activation, presumably through costimulation-like processes. In addition to such costimulatory molecules, there are accessory molecules that facilitate T-cell activation through adhesion of T cells to DCs. LFA-1 and CD2 may be good examples, which, in addition to a postulated signaling function, enhance TCR triggering by facilitating T-cell APC interactions. Interestingly, effector function of T cells occurs rather independent of costimulation, ensuring proper activity of effector cells in the periphery, where costimulatory molecules are scarce. Thus, T cells go through an initial phase of costimulation-dependent activation followed by costimulation-independent effector function.

3.2.2 Duration of Antigen Presentation

It has been shown that a single brief exposure to antigen allows T cells to undergo a full program of activation, proliferation, and effector cell differentiation. Yet, extended antigen presentation is essential for the generation of protective T-cell responses and also for the induction of CD28-independent T-cell activation as observed after viral infection. In fact, one of the key differences between pathogens and recombinant, nonreplicating antigens is the duration of antigen presentation. While antigens derived from viruses, bacteria, and other pathogens are presented for at least as long as the pathogens replicate, recombinant antigens are presented for much shorter time spans; peptides are, for example, usually only presented for a few hours. This, in part, explains the poor immune response usually obtained with recombinant antigens and also indicates why adjuvants enhance immune responses, since adjuvants, such as aluminum hydroxide or Freund's adjuvants, form antigen depots, leading to a prolonged antigen release. In addition to forming antigen depots, modern vaccines also contain substances that activate the innate immune system, as discussed in the next Section (3.2.3).

3.2.3 DC Maturation

DCs are cells that are potent in taking up and processing antigens. In addition, DCs are the most efficient cell type for the induction of protective T-cell responses. Yet, DCs are surprisingly efficient at inducing T-cell tolerance if they are not activated by additional stimuli. Thus, only activated DCs induce protective T-cell responses. When DCs are resting or immature, they induce T-cell tolerance rather than activation. The inability of immature DCs to trigger T-cell activation may in part be explained by reduced levels of costimulatory molecules; indeed, during DC maturation, costimulatory molecules such as CD80/CD86 are upregulated, leading to increased costimulation. Nevertheless, resting DCs do express significant levels of CD86 and it seems unlikely that absence of costimulation alone is responsible for inducing tolerance rather then immunity. Additional factors, such as lack of cytokine secretion by resting DCs or their short life span that leads to a short duration of antigen presentation are probably also contributing to the inability of immature DCs to induce protective T-cell responses.

Two types of stimuli cause activation and maturation of dendritic cells: cytokines and other proteins produced by T cells, macrophages, DCs, and/or other cell types and patterns associated with pathogens (PAMPs) recognized by specific receptors on DCs. Good examples of such patterns are LPS or other cell wall components of bacteria as well as the double-stranded RNA of viruses. The best described receptors for such patterns (PRRs) are toll-like receptors 1 to 11. Interestingly, different toll-like receptors appear to stimulate the immune system in slightly different ways. DCs, for example, express, amongst others, toll-like receptors 2, 4, and 9. For the induction of CTL responses, toll-like receptor 9 appears to be much more important than the other two receptors, while for enhancing antibody responses against allergens, toll-like receptor 2 appears to be most efficient.

Simulation of DCs and other APCs by toll-like receptors is most important for the early immune response, directing the type of immune response that is induced. Specifically, most toll-like receptors direct the immune response toward a Th1 type and CTLs, namely the type of T- cell response that is critical to rid viruses and bacteria. Many multicellular parasites are eliminated by the immune system mounting a Th2 response. In line with this, most parasites are not known to engage toll-like receptors.

Cytokines produced by activated T cells are playing a major role in reinforcement, sustaining and amplifying the type of response that has been initiated by the toll-like receptors. In this way, the innate and adaptive immune system interacts intimately early in the response and the adaptive immune system only becomes independent of the innate immune system once the T-cell response has reached a certain threshold required for a sustained response.

3.3 Extravasation

Once activated, T cells need to leave lymphoid organs and emigrate into tissues. A key step in this process is the trans-endothelial migration of lymphocytes. Three steps dominate this migration (Fig. 2). In the first step, lymphocytes attach loosely to the endothelial layer by way of interaction between selectins expressed on T cells and adressins expressed on endothelial cells. In this phase, lymphocytes roll over the endothelium of blood vessels. In the second step, lymphocytes become activated by local chemokines bound to the extracellular matrix on endothelial cells. This leads to cellular activation and increased avidity of LFA-1 to its ligand I-CAM, resulting in arrest of the cells at the local site and trans-endothelial migration (diapedesis). At the site of injury or infection, CTLs may then directly lyse target cells or inhibit pathogen replication by secretion of cytokines. Similarly, Th cells, if activated by local MHC class II expressing APCs, also secrete cytokines, chemokines, and other mediators, leading to increased permeability of the endothelial cell layer and further cell-recruitment. In addition, cytokines and chemokines may trigger local activation of APCs and effector cells, such as granulocytes and CTLs.

3.4 Delayed Type Hypersensitivity Reaction

A well-known example of T-cell activation, extravasation, and local release of

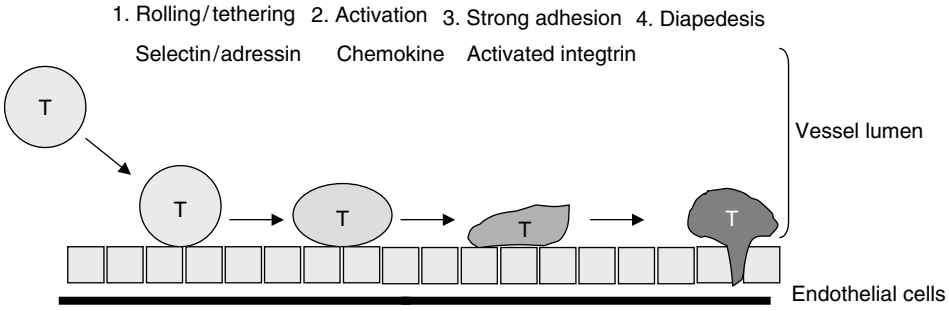

Fig. 2 Multistep model of lymphocyte activation for extravasation from blood into the tissue.

immunological mediators is the delayed type hypersensitivity reaction. Upon injection of proteins into the skin, antigen drains into T-cell areas of the lymph node, leading to MHC class II-associated antigen presentation. At the same time, Langerhans cells in the skin take up the antigen, process it, and transport it into the lymph node, further increasing antigen presentation. This leads to local activation of T cells. If the organism is exposed for the first time to the antigen, the kinetics of the T-cell response induced is slow and by the time activated T cells leave the lymph node, the antigen in the skin has been eliminated and no local reaction becomes visible. In contrast, in the presence of memory T cells, activated T cells leave the lymph node quickly while the injected antigen is still present in the skin. This results in a local inflammatory response, which is readily visible as a local rash and swelling, due to increased permeability of the vessels. Since no inflammatory response occurs in the absence of preexisting T-cell memory, this delayed type hypersensitivity (DTH) reaction is often used to measure T-cell memory and to probe for persistent infections, as is done with the tuberculin test for diagnosis of latent infection with tuberculosis.

3.5 Lymphoid Organ-like Structures in Chronic Inflammation

Induction and maintenance of T-cell responses usually requires the transport of antigen into lymphoid organs, where T-cell activation occurs. This is true both for the induction of protective T-cell responses against pathogens as well as for the generation of T-cell responses directed against self, potentially causing autoimmunity. For these latter autoimmune responses, however, the reverse may also occur, namely, that lymphocytes are attracted to self-antigens in the periphery, causing sustained T-cell responses and damage in the afflicted organs. An important molecule for this process is the chemokine BLC (CXCL13, BCA-1), which attracts B cells. Under normal conditions, BLC orchestrates the generation and maintenance of B-cell follicles in lymph nodes and spleen, by attracting CXCR5 receptor expressing B cells. B cells that have been stimulated by BLC express lymphotoxin β(LT-β), which is essential for the generation of follicular dendritic cells and formation of B-cell follicles. Around these B-cell follicles, T-cell areas are formed leading to the generation of the typical structure of lymphoid organs. Expression of BLC in the periphery

is sufficient to drive the generation of such structures within peripheral organs, causing chronic stimulation of self-specific T cells within these ectopic structures. Indeed, in a mouse model of lupus erythematosus, a severe autoimmune disease in humans, BLC expression was increased up to 10 000 fold in organs such as thymus and kidney, that are typically infiltrated by lymphocytes. It is likely that lymphoid organ-like structures observed in patients with Hashimoto's thyroiditis, type I diabetes, or rheumatoid arthritis may have a similar origin and are caused by local expression of BLC or lymphotoxin-β.

4
Mechanisms of T-Cell Mediated Immunity

4.1
Th Cells (CD4+)

Th cells have a limited ability to directly interfere with pathogen replication. Through secretion of cytokines, in particular IFNγ, Th cells can induce an antiviral state in neighboring cells, halting replication of viruses and intracellular bacteria. In addition, members of the TNF superfamily (TNF and Fas-ligand) may have the ability to cause apoptosis in infected target cells, also reducing pathogen replication. The most important function of Th cells is, however, the orchestration of the various antimicrobial effector cells (Fig. 3). Through the secretion of chemokines and cytokines, Th cells are able to recruit innate effector cells, such as macrophages, granulocytes, or eosinophils and activate DCs, enhancing T-cell priming. In addition, Th cells are able to cause isotype-switching in B cells and the generation of protective memory antibody levels. Moreover, Th cells also act directly on $CD8^+$ T cells facilitating the induction of CTL responses against weak antigens and enabling development of proliferation competent memory CTLs. Thus, although Th

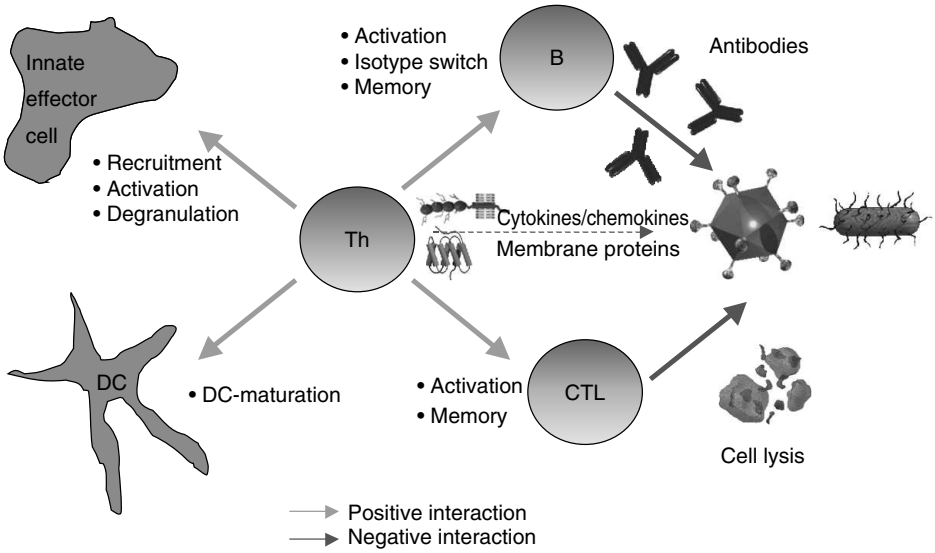

Fig. 3 Cross-talk between the innate and adaptive immune system and the critical role of Th cells in orchestrating the immune response.

cells have little immediate effector function, they are key cells for the induction and maintenance of immunity by activating an army of innate effector cells and facilitating the generation of B- and T-cell memory.

4.2 Cytotoxic T Cells (CD8+)

In contrast to Th cells, CTLs are key effector cells of the adaptive immune system. Similar to Th cells, CTLs are secreting a variety of chemokines, cytokines, and IFNγ enhancing cellular recruitment and activation as well as causing a local antiviral state. In addition, CTLs harbor lytic granules, which upon stimulation are released in a directed fashion at the immunological synapse onto the recognized target cells. The lytic granules contain a variety of proteins that can cause death of the recognized target cells. The most important proteins are perforin, which acts by ''punching'' holes into target cells as well as serine proteases belonging to the family of granzymes. Although it was originally thought that perforin mediates cell death by destruction of membrane integrity, it has recently become clear that the main function of perforin is to enable granzymes to enter target cells. This causes death of the target cells, because granzymes activate caspases, leading to apoptosis.

Granzymes are inactive at the low pH while they are stored in the granules and they only become activated once they are released from the granules, that is, in the target cells. The importance of the lytic perforin/granzyme pathway versus the secretion of cytokines by CTLs varies with the pathogen. For lytic viruses, which rapidly kill infected target cells, the perforin/granzymes pathway is of limited importance and cytokines and TNF family members are more important for protection. For nonlytic viruses, which do not kill the infected target cells, the perforin/granzymes pathway is more pivotal and cytokines as well as other soluble mediators play a minor role.

5 Silencing of the Immune Response: What Goes Up Must Come Down

So far, we have mainly been concerned with the buildup of protective T-cell responses. However, the silencing of ongoing immune responses to limit damage in the host caused by the immune system (immunopathology) is equally important. What mechanism(s) are available to switch off T-cell responses? For responses against acute infections, the most efficient mechanism is the elimination of antigen. Once the pathogen has been cleared from the host, the majority of T cells undergo apoptosis and, in the absence of further stimulation, the T cells become quiescent memory T cells (Fig. 4). As an additional mechanism, antigen-specific attenuation of T-cell responses by membrane-bound receptors has been postulated for CTLA-4, PD-1, a CTLA-4 homolog and further homologs of this family of receptors (e.g. BTLA). Indeed, mice deficient in the respective genes have a striking phenotype and rapidly develop symptoms of autoimmune disease. However, the mechanism of this attenuation is still a matter of debate. In fact, rather than downregulating T cells in an antigen-specific manner, receptors such as CTLA-4 may facilitate the induction of regulatory T helper cells that secrete anti-inflammatory cytokines.

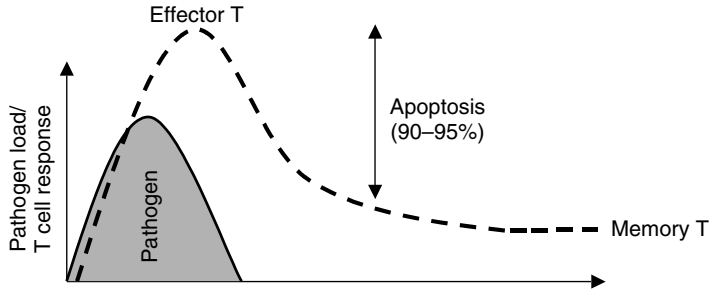

Fig. 4 Regulation of T-cell responses and establishment of memory.

TGF-β and IL-10 are the most potent immunosuppressive cytokines. Production of these anti-inflammatory cytokines has been shown to be of great importance during an infection with parasites, which may otherwise induce overshooting T cells responses resulting in the death of the host. The ambivalent function of immunosuppressive or anti-inflammatory cytokines is well illustrated by IL-10. On the one hand, acute infection of IL-10 deficient mice with Toxoplasma gondii or the malaria parasite *Plasmodium* results in a fulminate inflammatory response, causing death of the infected mice due to immunopathology usually kept in check by IL-10. On the other hand, due to increased inflammatory T-cell responses, IL-10-deficient mice are better protected from primary and secondary systemic infection with *Listeria monocytogenes* and show improved clearance of pathogens such as *Mycobacteria* or *Leishmania major* that usually persist in their hosts.

In case the pathogen cannot be cleared from the host, as is the case for the parasite *L. major*, the member of the TNF-receptor family Fas has been shown to be important by causing apoptosis of highly stimulated T cells, preventing their accumulation. Indeed, Fas-deficient mice amass antigen-specific T cells upon infection with *L. major*, resulting in grossly enlarged draining lymph nodes.

In conclusion, T-cell responses induced by acute infection that can be resolved by the host are usually downregulated by clearance of the antigen. Under condition of excessive antigen load or undue stimulation of innate immunity or when the pathogen cannot be eliminated, additional mechanisms may kick in, such as inhibitory receptors and, in particular, the production of anti-inflammatory cytokines.

6 T-Cell Memory

Upon infection or vaccination, specific T cells proliferate and expand as a population. Peak frequencies are usually reached within one or two weeks. Once the pathogen has been cleared, T-cell frequencies start to drop and more than 90% of the T cells undergo apoptosis. The remaining cells differentiate into memory cells and are maintained at relatively constant frequencies over extended time periods (Fig. 4). If the pathogen is reencountered, these T cells respond with accelerated kinetics, leading to an enhanced secondary

T-cell response. Hence the term ''T-cell memory''; the immune systems remember that it has previously responded to the pathogen.

This enhanced T-cell response is not only due to increased numbers of memory T-cell precursor. Memory T cells also show an altered physiology when compared to naïve T cells. Most importantly, memory T cells can secrete cytokines within hours after stimulation while naïve T cells require days for initiation of cytokine secretion. Moreover, memory T cells can be activated in the absence of costimulation, apparently due to a rearranged signal transduction machinery. Thus, if compared to naïve T cells, memory T cells are also more potent at the single-cell level.

Various memory T-cell subsets have been described. Particularly prominent is the concept of central versus effector memory T cells. Originally, it was thought that central memory T cells reside in lymph nodes and the spleen and rapidly respond with proliferation to antigen reexposure. Effector memory T cells, on the other hand, were suggested to reside in peripheral tissues and exhibit immediate effector function. Hence, effector memory T cells were thought to be mainly responsible for immediate protection against reinfection. However, this concept has meanwhile been challenged in many ways and it was found that central memory T cells are often found in peripheral tissues and exhibit similar immediate effector function as effector memory T cells. In addition, it was even reported that central memory T cells are more potent at mediating protection against reinfection than effector memory T cells. Thus, the physiological significance of the two types of memory T cells remains to be established.

The importance of persisting antigen for the maintenance of T-cell memory and for the balance between central and effector memory T cells has been a matter of extensive debate. Nevertheless, it is now emerging that memory T cells do not need persisting antigen for their survival. Yet, presence of persisting antigen keeps the T cells in a more activated state, facilitating maintenance of immediate effector function. Thus, optimal long-term protective T-cell memory is induced by viruses that persist at a low level in the host, such as lymphocytic choriomeningitis virus or cytomegalovirus. In fact, it is the chronically stimulated T cells that keep the virus in check and prevent widespread replication. Indeed, containment of persisting viruses and other pathogens is probably one of the most important tasks of T-cell memory. The importance of chronic antigen exposure for the maintenance of T-cell effector function is also illustrated by the examples described above of lymphoid organ-like structures in peripheral organs of patients with autoimmune diseases. It is the continuous antigenic exposure in an immunostimulatory environment that keeps T cells activated and capable of mediating tissue destruction.

In conclusion, upon elimination of the bulk of the antigen, most of the effector T cells undergo apoptosis and few of the cells differentiate into memory T cells. These memory cells are maintained at increased frequencies and are able to respond to antigenic reexposure with enhanced kinetics. One key function of memory T cells is to keep persistent infections under control and prevent widespread replication of the pathogens.

Primary Literature 378

Keywords

Automated
Automated immunoassays require complex, computer-controlled instrumentation that takes care of all repetitive steps such as sample handling, pipetting, washing, end point determination and the calculation of results. New larger machines integrate the functions of immunoassay analyzers and clinical chemistry analyzers into one system.

Binding Affinity
Binding affinity is the probability of association of a ligand (antigen) with a binding molecule (antibody). High affinity depends positively on the rate of association of the two molecules and negatively on the rate of dissociation of the complex formed.

Classification
In this context, ''classification'' refers to any system that may be used to explain how the very large numbers of different immunoassays are related to each other.

Epitope
An epitope is that portion of an antigen with which the binding site of an antibody (paratope) interacts specifically.

Hapten
A hapten is a low molecular weight antigen that is not inherently immunogenic.

Hybridoma
Monoclonal hybridoma cells are ''immortal'' cells that (in the present context) are capable of synthesizing antibodies with desirable properties. They are generated by fusing lymphocytes and myeloma cells, followed by dilution, culture, and selection steps to ensure enduring viability, homogeneity, and ability to secrete desirable monoclonal antibodies.

Immunoglobulin Structure
All immunoglobulin molecules are glycoproteins with similar characteristic complex structures that are rugged and flexible. They consist of multiple, paired domains that are all derived from ''the immunoglobulin fold,'' a protein structural motif also found in many other proteins.

Interference
By interference is meant the phenomenon whereby an incorrect result is obtained in an immunoassay because of the presence, in the sample being tested, of a substance or substances (other than the analyte) capable of interacting with assay reagents so as to influence their normal roles.

Label
The term ''label'' is usually applied to the labeled antigen, labeled hapten, or labeled antibody employed as a reagent in immunoassay.

Microarray
In the context of immunoassay methodology, a microarray is usually an array or matrix of microdots each coated with a different specific antibody or antigen.

Monoclonal Antibody
A homogeneous population of antibody molecules, each with identical binding affinity and specificity, synthesized by a monoclonal cell line.

Multiplexed
Multiplexed immunoassays are capable of detecting or measuring two or more analytes following the execution of a single analytical procedure that usually has no additional steps as compared to an ordinary assay. Multiplex is a synonym of multiple.

Paratope
A paratope consists of complementarity determining regions (CDR) of the variable domains of an immunoglobulin and is that portion of an antibody that constitutes an antigen binding site.

Polyclonal Antibody
A heterogeneous population of antibody molecules raised by immunizing a suitable animal with a specific antigen.

Rapid Test Device
Rapid test devices (RTD) are small constructs usually consisting of one or more components, including moulded plastic structures, membranes, adsorbent strips, absorbent pads, and immobilized (or otherwise incorporated) assay reagents. An immunoassay formulated as a RTD enables the detection of tiny quantities of specific molecules at virtually any location by untrained persons.

Reagent-excess
In reagent-excess immunoassays, the principal reagents, such as immobilized antibody and labeled antibody or labeled antigen, are used in excess. Most reagent-excess immunoassays may also be described as ''sandwich'' immunoassays.

Reagent-limited
For reagent-limited immunoassays, the principal reagents, such as immobilized antibody and labeled antibody or labeled antigen, are used at limited concentrations, and a plot of ''label bound'' against analyte concentration displays an inverse relationship. Reagent-limited immunoassays are commonly referred to as ''competitive'' immunoassays. Separation-free immunoassays are usually ''reagent-limited.''

Separation-free
A separation-free (homogeneous) immunoassay has no separation step. Separation-free immunoassays are usually ''reagent-limited.'' In a normal immunoassay, after incubation of reagents with analyte, bound label must be separated from free label to enable measurement of the bound fraction. In separation-free immunoassay, the binding of label to antibody modulates the activity of label such that analyte concentration determines *total* label activity.

Solid Phase
In immunoassay, a solid-phase component may be the internal wall of a tube or well, a bead or microparticle, a membrane or a thread. Linking a basic assay reagent such as antibody or antigen to a solid-phase component allows the easy separation of bound from free label, thereby facilitating the accurate measurement of bound (or free) label.

Standardization
By standardization is meant the development and validation of assays in such a way that all assays for the same analyte give the same (numeric) results if applied to the same samples. The same results should be obtained whether the assays were developed and manufactured by different companies, used at different locations, operated by different users, or used at different times.

Structural Complementarity
Structural complementarity is the term used to explain the high affinity binding of the paratope of a specific antibody to the epitope of an antigen. The paratope and epitope have complementary shapes, complementary distributions of electric charges, and opposing groups that form good noncovalent bonds. Structural complementarity, in all its variety and complexity, explains all strong and spontaneous molecular associations and is therefore an essential part of the ultimate explanation for all biological processes.

Specific, biologically related, intermolecular interaction is the basis of all ''binding assays,'' recombinant DNA procedures, and, accompanied by catalysis, of enzymatic analysis. ''Binding assays,'' also referred to by the term *saturation analysis*, depend on the ''bio-recognition'' of analytes by high affinity, specific binding proteins. In the last forty years ''protein binding assays'' have found so many applications in diverse areas of biochemical and chemical analysis that they now represent a standard analytical principle, like colorimetry or chromatography.

While there are many kinds of high affinity, specific binding proteins in nature (hormone receptors, for example), the special properties of antibodies have made them the most popular choice by far, for such methods. The term ''immunoassay'' applies to measurement procedures that use antibodies as specific binding reagents, as well as to assays that use antigens for the detection or quantification of specific antibodies. It is because of the extraordinary variety, specificity, and affinity of antibody–antigen binding reactions, that immunoassays are used for routine analyses and for research purposes throughout the biological and medical sciences.

Often an immunoassay procedure is chosen to measure a particular analyte because no other type of assay is technically feasible, which is true for specific antibodies, for most proteins and for many other complex biomolecules. But frequently, immunoassays are used because they match or exceed analytical and practical requirements and are more convenient and cost-effective than any alternative method.

When a broad perspective is adopted, it is clear that the history of immunotechnology as applied to the detection and quantitation of antigens did not begin with the invention of radioimmunoassay in the late 1950s. Rather, experimental immunologists have always used specific antibodies and ''purified'' antigens in their investigations, and major developments with respect to ''immunoassay methodology'' occurred when these were applied clinically and/or formulated to maximize their utility to clinical microbiologists, clinical chemists, and others. Table 1 lists some of the significant advances in this long history of the development of immunoassay methodology.

1
Antibodies for Immunoassays

1.1
Immunoglobulin G Structure

Antibodies, also defined as immunoglobulins and found in blood and other body fluids of vertebrates, are essential components of the adaptive, humoral immune system. Immunoglobulin G (IgG), the class of antibody used predominantly in immunoassays, is a 150 000 Da glycoprotein containing two identical heavy (H ~420 residues) and two identical light (L ~215 residues) polypeptide chains. The two identical antigen-binding sites (also called paratopes) of IgG are composed of the atoms of about fifty amino acid residues found in groups (complementarity determining regions, CDR) scattered along the variable segments of the H and L chains. In the 3-D structure of all immunoglobulins the six CDR occur as loops and it is CDR variability that accounts for almost all of the immense range of antibody specificity.

For analytical purposes, IgG molecules can be linked covalently to labeling substances and to solid-phase materials by any of a range of standard chemical procedures. They also readily bind noncovalently to plastics and glass to give ''antibody coated'' tubes, wells, or beads.

Immunoglobulins are flexible molecules, and this facilitates their binding simultaneously to two (or more) adjacent identical antigens on the surface of a pathogen and enables the aggregation of soluble antigens. While all interdomain regions can flex and bend, the greatest flexibility is associated with the ''hinge regions'' of the H chains, near the C-termini of the L chains. These regions are highly susceptible to proteolytic cleavage, and pepsin specifically hydrolyzes a site located below the inter-H chain disulphydryl links to give $F(ab')_2$ dimers that are easily reduced to give Fab' fragments ($M_r \sim 50\,000$). Fab' fragments have at least one sulphydryl group (–SH) distally located from the binding site, which can be used to establish a covalent linkage to labeling molecules or solid-phase materials. Also because of their relatively small size and reduced tendency to bind ''nonspecifically,'' Fab' fragments are highly suitable for the preparation of soluble reagents for use in immunoassays.

Fv fragments ($M_r \sim 25\,000$), which include only the variable segments of the

H and L chains, are minimal antibodies. Recombinant DNA methods enable the preparation of stable, single-chain Fv (sFv) fragments for any monoclonal antibody, and of chimeric proteins incorporating antibody-binding sites. (Phage display techniques allow the creation of vast repertoires of genes coding for heavy and light chains, *in vitro* selection of recombinant clones producing antibody of a desired specificity, and *in vitro* ''affinity maturation.'')

1.2 Monoclonal, Polyclonal, and Anti-hapten Antibodies

Although during the 1980s the use of monoclonal antibodies in new immunoassays increased dramatically, even now in the twenty-first century, polyclonal antibodies are still preferred as secondary reagents in all commercial immunoassays, and is a primary reagent in a large minority of immunoassay kits. Obviously, differences with respect to cost, ease of preparation and availability are still sufficient to outweigh the advantages (homogeneity and continuity of supply) associated with monoclonal (or recombinant) antibodies.

Immunoassay antibodies come from a range of species including mice, rabbits, goats, and sheep. Avian IgY class antibodies, which may have much lower ''nonspecific binding properties'' are also used, and camel antibodies, which lack light chains, may become significant in the future. Usually, monoclonal antibodies are raised in mice but all the prerequisites are available for the use of rats.

The power and versatility of immunoassays is largely dependent on the availability of specific antibodies for most biologically important molecules with a distinctive chemical structure and of molecular weight >150 g mol^{-1}, whether or not they are inherently immunogenic. Immunologically, haptens are defined as molecules of limited molecular weight that are not naturally antigenic, but when conjugated to a carrier (bovine serum albumin or BSA for example, with 20–30 hapten molecules per molecule of BSA) give an immunogen that can be used to generate antibodies that specifically bind free hapten with high affinity. This approach is also highly effective for larger molecules that are weakly immunogenic. Therefore, antibodies for molecules that are newly identified or synthesized for the first time are readily prepared, in most cases.

2 Antibody–antigen Binding

2.1 Structural Complementarity

Antigen–antibody interactions are reversible and for binding to be defined as high affinity there must be a combination of easy association and reluctant dissociation. Association can be regarded as occurring in two phases, with the first requiring the overcoming of repulsive forces and the second involving the establishment of multiple hydrogen, ionic, and van der Waals attractive interactions between atoms on the antibody-binding site (paratope) and the antigenic determinant region (epitope).

When the epitope of a large protein antigen is bound in a high affinity complex with a paratope specific for it, the apparent area of close contact is about 700 to 900 Å^2, with about 20 amino acid residues on both reactants apparently participating.

An appropriate pH, which is usually near pH 7, ensures that acidic and basic groups on both species are suitably dissociated or associated. However, the contribution to binding of any close sets of opposing amino acid residues may be either negligible or crucial and this may account for the fact that a genetically determined variation in an antigen may render it virtually undetectable by an immunoassay. For example, Pettersson and coworkers discovered that, in a significant subpopulation of normal women with a genetic variant of luteinizing hormone (LH), LH was almost undetectable when measured with an immunoassay employing a particular kind of monoclonal antibody.

When the high affinity complex is between a small antigen (hapten) and its specific paratope, the hapten is found to be located in a pocket, cavity, or groove on the antibody surface. Indeed, this may be an absolute requirement for *high* affinity. When bound, the hapten is surrounded by functional groups of the peptide residues and backbone that are structurally complementary to adjacent portions of the hapten molecule. Frequently, to give the number of weak bonds to the hapten that are necessary for tight binding, the hapten is buried to the extent of 80 to 90%, or even greater. Nevertheless, as established by Arevalo and coworkers, other compounds with significant structural differences from the original specific hapten, may be capable of binding tightly to the same paratope, provided they also are sufficiently complementary with respect to size, shape, and charge distribution.

As binding of epitope to paratope occurs, there may be significant structural adjustments of the paratope (and of the epitope) and this is termed *induced fit*. However, frequently there is still sufficient interstitial space to accommodate water molecules or ions, some of which may contribute significantly to binding. Therefore, the ionic composition of buffers may be relevant to the selection and performance of an antibody, and optimal assay conditions can only be estimated experimentally.

2.2 Molecular Mobility Influences Binding

Any interaction between antibody and antigen must be preceded by a collision. The rate at which collisions occur is dependent on rates of diffusion, which, in turn, are influenced by molecular mass and shape, temperature, and, of course, on whether both reactants are mobile or not. Therefore, since smaller molecules diffuse more rapidly, haptens tend to associate more readily with their specific antibodies than with large antigens, and hapten analytes associate more readily than the large hapten-enzyme conjugates used as labels in enzymeimmunoassays. In addition, antigen–antibody interactions reach equilibrium much more slowly when the antibody or antigen is immobilized to a solid phase as opposed to when both are free to diffuse. Consequentially, many automated immunoassays, which require short incubation times, involve the use of microparticulate solid-phase media and regular mixing, or are designed such that the binding reaction occurs in liquid phase and separation is effected later.

2.3 Epitopes

Each large antigen has a theoretically unlimited number of epitopes, a number that is limited in practice by immune tolerance in the immunized animal toward surface regions that share structural features with self-proteins. It is also difficult to differentiate between overlapping

epitopes. Structurally, protein epitopes are often very similar to paratopes, being made up of a number of amino acid residues scattered, singly or in small groups, along the amino acid sequence, but close together on the surface of the intact antigen. Thus, many epitopes are ''discontinuous.'' However, a single short peptide may represent a large fraction of an epitope and may, in isolation, be specifically bound by an antibody raised against the whole protein that it represents. Correspondingly, antibodies raised against such a peptide may bind to the region of the cognate protein containing the same sequence. Such epitopes may be referred to as ''continuous.'' Not unusually, continuous epitopes correspond to exposed termini.

The chemical nature of epitopes is highly relevant to the development of sophisticated vaccines, and is also pertinent to immunoassays. For example, assays designed to detect specific antibodies against well-characterized viral pathogens (especially HIV), may employ single peptides (or more often sets of carefully chosen peptides), immobilized and/or linked to a labeling substance, instead of whole viral antigens. This allows precisely defined epitope specificity.

3 Labeling Substances

Although, as is explained further below, many immunoassays employ no discrete labeling ''compound,'' immunoassays only came ''of age'' with the invention of radioimmunoassay by Rosaleen Yalow and Roger Ekins in the late 1950s, and the gradual development of reagent excess, sandwich assays in the 1970s. During this period also, data obtained with the aid of high-throughput immunoassays with lower detection limits of 10^{-9} to 10^{-15} M helped to revolutionize many branches of biological and medical science.

The sophistication of current immunoassay methodology allows the assay developer a wide choice of labeling substances and assay endpoints, but a small number of label types dominate. Crucial attributes of labels include ease of use and the availability of simple procedures and suitable equipment, and the ability to provide very high specific activity, that is, a very strong signal per unit mass of label. These attributes are provided to a greater or lesser extent by enzymes, chemiluminescent compounds, fluorescent compounds, latex particles, microspheres, and radioisotopes. Of particular interest to the future are the range of ''rare earth'' ions that can be used, each with a distinct peak wavelength of fluorescent light, facilitates dual and multiassays that simultaneously measure two or more analytes. Similarly, a set of populations of microspheres with fixed intensities of one or two fluorescent dyes, allows multiplexed (up to ''100-plexed'') immunoassays when measured in flow-cytometry systems with two lasers.

Ligands, such as biotin, are also used as primary labels in combination with another label type that provides the endpoint. Table 2 lists a selection of general-purpose labeling substances (including atoms, ions, small and large molecules, and chelates) and some of the methods used for detecting and measuring them.

4 Classification of Immunoassays

4.1 Nomenclature

The names of immunoassays can be confusing and make it difficult to understand

Tab. 2 Some biomolecules, compound, ions, and other substances used for labeling and methods used to measure them.

Type	*Substance*	*Endpoint detection*
Enzyme	Alkaline phosphatase	Choice of endpoint including: amplified colorimetric colorimetric electrochemical luminometric visual assessment
	β-D-galactosidase	Choice of endpoint
	Glucose-6-P dehydrogenae	Colorimetric
	Horseradish peroxidase	Choice of endpoint
	Malate dehydrogenase	Colorimetric
Fluorescent	Fluorescein and other fluorescent dyes chemically coupled to antibodies or antigens, or/and in microspheres	Fluorimetric Polarimetric–fluorimetric Fluorescence flow cytometric
	Rare earth ions/chelates Dy^{3+}, Eu^{3+}, Sm^{3+} or Tb^{3+}	Time-resolved fluorimetric
Ligand	Biotin derivative	Avidin-acridinium ester, luminometric Avidin-enzyme, choice of endpoint Avidin-Eu^{3+} chelator, TR fluorimetric
	FITC	AntiFITC-enzyme, choice of endpoint
	oligonucleotide	Polymerase chain reaction or other amplification, choice of endpoint
Luminescent	Acridinium ester	Luminometric
	Isoluminol derivatives	Luminometric
	Ruthenium(II) chelate, trispropylamine	Electroluminometric
Microparticle	Colloidal gold	Visual assessment
	Colored latex	Visual assessment
	Latex etc.	Particle counting Visual assessment
Radioisotopic	^{3}H	Liquid scintillation counting
	^{125}I,	Solid scintillation counting
	^{125}I-Bolton & Hunter reagent	Solid scintillation counting

similarities and differences, and the diversity of immunoassay designs. In general, most assay names contain ''immuno,'' the combining form of the adjective ''immune,'' and another combining word indicating the type of label employed, for example, radioimmunoassay (RIA) or enzyme immunoassay (EIA). If an alternative biological binding protein to an antibody is employed, such as a hormone receptor, the corresponding name is radioreceptor assay.

The use of the terms RIA and EIA is usually (but not always) restricted to reagent-limited, competitive assays (see below), and reagent-excess assays (see below) are commonly distinguished by reversing the order of the combining forms,

as in immunoradiometric assay (IRMA), immunofluorometric assay (IFMA), or immunoenzymometric assay (IEMA). The term *immunometric assay* is used to refer to reagent-excess assays in general. However, similar names have occasionally been used for competitive assays with labeled antibody.

The acronym ELISA (enzyme-linked immunosorbent assay) is generally applied to all kinds of microtiter plate assays with enzymatic labels and, when encountered, cannot be relied upon to indicate a particular assay mechanism. For clarity, EIA is to be preferred over ELISA for competitive assays equivalent to RIA and IEMA for reagent-excess assays equivalent to IRMA.

Commercially developed immunoassays with patented features are often named with ''acronyms'' that may or may not be defined. Three separation-free assays are EMIT® (enzyme modulated immunotest), FPIA® (fluorescence polarization immunoassay) and CEDIA® (combined enzyme donor immunoassay).

4.2 The Variety of Immunoassay Formats

The versatility of immunoassays is made possible largely by the wide variety of formats that can be implemented for assays of similar basic design. For example a basic, two-site, reagent excess, sandwich assay design for an antigen analyte may be used for high performance, high throughput, laboratory-based applications; or for simple, test devices to be used by untrained persons and sold over the counter in normal retail outlets. Much of the variety in format is dependent on the different solid-phase materials and configurations (e.g. microtiter wells, microparticles, membranes or simple test devices), on the different labels used (e.g. radioactive, fluorescent, enzymatic or colored particles), and on how the endpoint is measured (with a complex electronic instrument or visually).

4.3 Representing Assay Complexes in Text

In this article, the primary reagents used and the complexes of antibodies, antigens, and other components that form during the operation of immunoassays will be represented in the text by means of a standard notation system (not all aspects of which are exploited here).

According to this system, the analyte is shown in bold print, for example, ''**Ag**,'' ''**Ha**'' or ''**Ab**'' for general antigen, hapten and antibody analytes, or more specifically, human chorionic gonadotropin (**hCG**) for the human pregnancy hormone. Where any one of a number of labeling substances could be used, it is represented by ''L,'' otherwise an abbreviation such as ''enz,'' or ''^{125}I'' is used.

Standard abbreviations are used when the class (IgG, IgM) or type of antibody (monoclonal, mAb, mAb1, mAb2), antibody fragment (Fab') or single-chain recombinant fragment (scFv) is to be specified. The origins of antibodies can be shown with single letter abbreviations (e.g. goat, G; human, H; mouse, M; rabbit, R; sheep, S) if this is relevant. The names of unusual components, or components that must be more exactly specified, can be abbreviated or spelled out.

The hyphen (''-'') sign is used to indicate associations established before commencement of the assay such as an antibody-label conjugate or an antibody-enzyme conjugate (Ab-L, Ab-enz, respectively) or an antibody immobilized on a solid phase (sp-Ab). In contrast, the en

dash ("–") represents associations formed during the course of the assay procedure. For example, the final complex of a solid-phase ELISA for an antigen is described as: sp-Ab–**Ag**–Ab-enzyme. For a reagent-limited competitive assay for a hapten analyte two complexes are formed, sp-Ab–**Ha** and sp-Ab–Ha-L, and, as explained below, only the complex that does *not* contain the analyte is measured.

4.4 The Four Main Groups of Immunoassays

Table 3 represents a system whereby most, if not all, immunoassays can be classified into four groups. In this context, it should also be borne in mind (as mentioned above) that binding proteins other than antibodies can be used as specific binding reagents in assays that are the exact equivalents to those mentioned below. For example, intrinsic factor and β-lactoglobin are used as specific binding reagents in group 2-type assays for vitamin B_{12} and folate, respectively. Also, a combination of an antibody and a particular lectin may be used to measure specifically glycoproteins with particular carbohydrate side chains, by means of a reagent-excess, sandwich assay.

Most quantitative immunoassays developed for research purposes or for applications of limited scale are simple immunoprecipitation assays (Group 1), reagent excess, sandwich assays with either direct or indirect labels (Group 2) or reagent limited, competitive assays with a separation step (Group 3). The first three groups have long been very well represented among commercially developed immunoassays sold as

Tab. 3 Classification of immunoassays into four groups.

Group	*Type*	*Examples*
1. Label free	Agglutination	Hemagglutination Latex agglutination
	Precipitation	Ouchterlony gel diffusion Rocket immunoelectrophoresis Immunoturbidimetry/nephelometry
	Immunosensors	Resonant mirror waveguide (IAsys™) Surface plasmon resonance (BIAcore™)
2. Reagent excess	One-site	Immunostaining Western blotting Fluorescence activated flow cytometry
	Two-site	Immunoenzymometric assay, (IEMA, ELISA) Immunofluorometric assay Immunoradiometric assay
3. Reagent limited	Labeled antigen or antibody	Radioimmunoassay Enzymeimmunoassay Fluoroimmunoassay
	Separation free	EMIT, CEDIA, FPIA
4. Ambient analyte	Microarray/microchip	Microspot®

stand-alone kits or run on automated analyzers.

4.4.1 **Label-free Assays**

Provided that the concentrations are sufficient, the molecular complexes ([Ab–Ag]*n*) generated by antibody–antigen interaction are visible to the naked eye, but smaller amounts may also be detected and measured due to their ability to scatter a beam of light. The formation of complexes indicates that both reactants are present, and in immunoprecipitation assays a constant concentration of a reagent antibody is used to measure specific antigen ([Ab–**Ag**]*n*), and reagent antigens are used to detect specific antibody ([**Ab**–Ag]*n*). If the reagent species is previously coated onto cells (as in hemagglutination assay) or very small particles (as in latex agglutination assay), ''clumping'' of the coated particles is visible at much lower concentrations.

A variety of assays based on these elementary principles are in common use, including Ouchterlony immunodiffusion assay, rocket immunoelectrophoresis, and immunoturbidometric and nephelometric assays. The main limitations of such assays are restricted sensitivity (lower detection limits) in comparison to assays employing labels and, in some cases, the fact that very high concentrations of analyte can actually inhibit complex formation, necessitating safeguards that make the procedures more complex. Some of these Group 1 assays date right back to the discovery of antibodies (Table 1) and none of them have an actual ''label'' (e.g. Ag-enz).

Other kinds of immunoassays that are label free depend on immunosensors, and a variety of instruments that can directly detect antibody–antigen interactions are now commercially available. Most depend on generating an evanescent wave on a sensor surface with immobilized ligand, which allows continuous monitoring of binding to the ligand. Immunosensors allow the easy investigation of kinetic interactions and, with the advent of lower-cost specialized instruments, may in the future find wide application in immunoanalysis.

4.4.2 **Reagent-excess Assays**

Group 2 contains assays that are typified by the use of an excess concentration of labeled antibody or antigen for the detection specific antigen or antibody.

''One-site'' reagent-excess assays include western blotting, whereby proteins absorbed to nitrocellulose filters are located by ''probing'' with labeled specific antibodies (nitrocellulose-**Ag**–Ab-L) and immunostaining, such as immunofluorescence assay whereby antigen in a tissue section is visualized with specific antibodies conjugated to fluorescein (cell matrix-**Ag**–Ab-fluorescein). Fluorescence-activated cell sorting (FACS) also depend on specific immunostaining of free-floating cells (**cell-Ag**–Ab-fluorescein).

However, most often, separate binding reactions specific for two different sites on the analyte are involved, giving rise to a tri-molecular, or larger, complex with the analyte in the middle, hence the terms ''two-site assay'' and ''sandwich assay.'' For example, two monoclonal antibodies against different, distally located epitopes on the analyte may be used to detect a protein hormone such as hCG with high specificity (sp-mAb1–**hCG**–mAb2-L). Similarly, two-site assays can be used to detect specific antibodies of a particular immunoglobulin class or subclass. For example, a purified allergen and an antibody against human IgE may be used to detect specific antibodies of the IgE class that bind to the allergen in question (sp-allergen–**IgE**–Ab-L). Please note also

that to detect viral (e.g. HIV) infection, the antigen employed may be derived from a crude viral lysate, be prepared by a recombinant method; or be a synthetic peptide corresponding to an appropriate viral epitope, or a defined set of such peptides (see Sect. 2.3).

Assays to detect specific antibodies that employ immobilized-antigen to capture the analyte antibody and labeled antigen to titrate the bound antibody via its free antigen-binding site (IgG) or sites (IgM or IgA) are, strictly speaking, two-site assays (sp-Ag–**Ab**–Ag-L). However, since all sites on a single antibody are identical, such ''antibody bridge'' assays may be regarded as resembling one-site assays with respect to their specificity. ''Antibody bridge'' assays are very suitable for the early detection of viral infections such as HIV because IgM class antibodies are prominent in the early immune response, and in such assays the captured antiviral IgM antibodies may each bind multiple copies of the labeled antigen, enhancing the lower detection limit.

4.4.3 Reagent-limited Assays

Group 3 contains reagent-limited assays, typified by classical RIA. These are also commonly referred to as *competitive assays* and may have labeled antigen or labeled antibody. They are used to measure the concentrations of antigens or, more commonly, of smaller analytes such as steroids or drugs. In contrast to almost all other immunoassays, the immune complexes measured or detected (sp-Ab–Ag-L or sp-Ag–Ab-L) do not contain the analyte and, therefore, all such assays give inverse (i.e. falling as opposed to rising) standard curves when the concentration of bound label is plotted against increasing analyte concentration. Because of their ''indirect'' nature, competitive assays are inherently less sensitive than reagent-excess assays.

However, competitive assays can readily be designed to obviate the need for a separation step before label measurement, and such assays are referred to as *separation-free* or *homogeneous assays*. To avoid the need for a separation step, the binding reaction must influence the ability of the label to generate the endpoint signal. Ideally, such modulation should be 100% efficient and the limited lower detection limits generally achievable testify to the fact that, in general, this is not realized. Separation-free assays include the commercial systems EMIT, FPIA, and CEDIA which are widely employed in the manual and automated measurement of therapeutic, toxic, and illegal drugs. (See also Sect. 5.2.)

4.4.4 Ambient Analyte Assays

Ambient analyte immunoassays (Group 4) were proposed by Roger Ekins and are performed under conditions in which the concentration of immobilized captured antibodies (or antigen molecules) is so low that, as analyte binds to them, the concentration of analyte in the reaction medium is unaffected. As with many receptors in endocrine systems, fractional binding site occupancy is independent of both the amount of capture agent and reaction volume. For such a system, very high specific activity, fluorescent labels are necessary, and the small amount of capture antibody (or antigen) may be coated at very high density within a ''microspot,'' facilitating the development of microarray-based multianalyte systems. A range of multianalyte microassay immunoassay systems for clinical applications have been proposed and are under development by different groups, but many do not

correspond exactly to the kinetic aspects of Ekins' model.

5 Established Immunoassay Systems

Many immunoassay systems used in human clinical laboratories were first introduced in the 1970s and 1980s and have had long lives. For example, the separation-free systems EMIT (based on glucose 6-phosphate dehydrogenase labels) and FPIA were first described in the early 1970s and are still in widespread use across the world.

5.1 Automated Systems

Early clinical immunoassay analyzer systems, which provided automation of repetitive steps such as pipetting and washing, soon led to fully automated "batch analyzers;" and more recent systems are "random access." Sample and reagent volumes have also decreased and incubation times have shortened. The panels of analytes are now more extensive, so that hormones, specific antibodies and tumor markers may be available on a single instrument. New larger machines integrate the functions of immunoassay analyzers and clinical chemistry analyzers into one system.

Another trend has been away from the colorimetric determination of endpoints to chemiluminescent-based systems, whether to measure the activity of an enzyme label (e.g. DPC Immulite®) or to directly measure a luminescent label incorporating acridinium ester (Bayer ADVIA Centaur®) or Ruthenium(II) chelate (Roche Diagnostics Elecsys®).

The precision of automated immunoassays has improved in parallel with the above developments. As reported by Wheeler in 2001, the results of the UK National External Quality Assessment Schemes indicate that levels of within and between sample assay precision of less than 5% are now commonly achievable over much of the concentration range of analytes such as luteinizing hormone.

5.2 General Laboratory Assays

Most immunoassays in use today are variations on reagent-excess two-site systems for the measurement of larger antigen analytes and specific antibodies. In addition, reagent-limited assays are employed for the measurement of smaller molecules such as steroids or common drugs, usually with labeled hapten, rather than with labeled antibody. For the measurement of low concentrations of analyte (nmol L^{-1} and below), assays with a separation step (usually involving antibody immobilized on a solid phase) are used. All of these formats, adapted for use on 96 well microtiter plates, are operated manually in many laboratories for a huge range of applications covering all areas of routine and research biology. In some areas with high throughput, such as human clinical chemistry, they have been adapted to the automated systems described briefly above; in others they have been adapted to give the rapid, easy-to-use tests described below.

For small analytes such as steroids in the low pmol L^{-1} range, an assay with an extraction step to minimize sample matrix effects is to be preferred. Radioactive labels are now rarely used outside large laboratories where the appropriate traditions, facilities, and expertise persist.

Separation-free, reagent-limited immunoassays dominate in some areas, particularly for drug screening when concentrations are often in the μmol L^{-1} range. The most widely used systems have been EMIT®, FPIA® (Abbot Laboratories) and CEDIA®.

EMIT®, is a registered name of the Syva Corporation and is an acronym for ''enzyme multiplied immunotest.'' EMIT® is almost as old as EIA and dates from the classic paper of Rubinstein, Schneider, and Ullman in 1972. The invention of EMIT is one of the most important milestones in the history of immunoassays. In one stroke, radioisotopes were avoided, procedures simplified, ''turn-around-times'' greatly reduced, and automation on standard clinical chemistry analyzers made feasible.

CEDIA® is a major competitor of EMIT that depends on a detailed understanding of enzymology and protein structure. To devise CEDIA, recombinant DNA technology was exploited to produce new strains of *Escherichia coli* synthesizing inactive variants of β-D-galactosidase. These were of two complementary kinds, large fragments (enzyme acceptors, EA) and small fragments (enzyme donors, ED). Some matched pairs of EA and ED fragments could associate readily to give fully active enzyme and these were exploited (with EA as label) to develop a new, versatile separation-free immunoassay system, that is suited to automation by means of many general-purpose clinical analyzers.

There are also variations of standard immunoassays that play important specific roles in basic research. One example is the ELISPOT assay that for the last 20 years has been used in immunology research laboratories to quantify T-cell immune responses in individuals infected with different pathogens. ELISPOT tests are crucial to the evaluation of vaccines and other therapies when they are under trial, and are contributing to the fights against diseases such as AIDS.

5.3 Simple to use Test Devices

Many of the most impressive inventions involve the simplification of a previously complex task, but a long road with a series of separate inventions or developments may be necessary in some cases. Searching a database for articles on pregnancy tests reveals that in the 1950s live toads or frogs were used and that days passed before results were obtained. Obviously, and to say the least, such tests required many steps, laboratory facilities, and a skilled technician. Now the ''patient'' just holds a simple plastic ''rapid test device'' (RTD) in her urine stream for a few seconds, and minutes later she has the result.

The adoption of immunoassays, such as latex agglutination tests, to detect the pregnancy hormone hCG in urine was an important first step on the road. Later came dipsticks with multiple steps and reagents, and liquid waste to dispose of. Still later came what is now the ''Beckman Coulter Hybritech ICON® hCG test,'' which combines simplicity of operation and a low detection limit in a reagent-excess IEMA with two monoclonal antibodies, an alkaline phosphatase label, and a visible result. Two drops serum or 5 of urine, appropriately prediluted, are added to a simple small test ''pot.'' After two further reagent additions and washes with a simple dropper and suitable short delays, one colored dot indicates a valid negative result and two dots indicate a pregnancy. All liquid waste is retained in the ''pot.''

One-step operation, like that described above, arrived with the development of the

Unipath ClearView® test device. There are no liquid reagents or wash solutions to add and no need to precollect the urine sample. The ''mobile'' antibody is linked to intensely colored microbeads, obviating the need for a color development step. The simple RTD hides a basic reagent-excess sandwich immunoassay and has all the reagents preloaded, ready to be set in motion by the addition of water, and all the water needed comes with the urine sample.

Like for the ICON® RTD, there are now many similar devices from many companies and these have been adapted for a range of tests including fertility monitoring by detecting the preovulatory surge of LH in women. Similar RTDs are also widely used to detect specific antibodies for infectious diseases such as HIV infection, Lyme disease, etc.

6 Immunoassays of the Future

6.1 Multiplexed Immunoassays

Immunoassays capable of detecting simultaneously two or up to 10 or more analytes have been available for many years. These include the extraordinary MAST® system with up to 35 different allergens coated on cellulose threads for detecting elevated levels of specific IgE class antibodies in human serum. However, many of the multiplexed immunoassay systems of the future will be fully quantitative, capable of detecting larger numbers of varied and distinct analytes, and automated.

Developments in multianalyte microarray immunoassay systems (see also Sect. 4.4.4) have benefited from parallel advances in the methodology of genomics and proteomics. Computer controlled equipment is available for the immobilization of just hundreds of capture molecules per microspot on heterogeneous arrays of hundreds of spots. There are also automated liquid pipettors that deliver submicroliter volumes of reagents and of samples to be analyzed, where and when required. In addition, charge-coupled device (CCD) detectors can scan and quantify luminescent or fluorescent light emission from each spot in a large array. Planar waveguide evanescent field technology enables microarray assays without separation or washing steps.

Multiplexed assays based on heterogeneous populations of microbeads have also been developed in a number of laboratories. These benefit greatly from the availability of diverse sets of identifiable microspheres. Each set or population of microspheres may incorporate one or two fluorescent dyes at set densities (enabling the creation of a large number of sets) and is easily and specifically quantifiable by a suitable flow cytometer. Recent flow cytometers, dedicated to suspension-array assays, have dual lasers and are capable of up to 100-plexed operations. Immunoassays for the measurement of specific antibodies and antigens developed for such systems usually correspond to Group 2 and 3 assays as described in Sect. 4.

6.2 New Assay Principles and Systems

The detailed history of immunoassay methodology is dotted by hundreds of reports of new and original systems, labels and detection methods, each presented as offering multiple advantages such as ease of use, low detection limit, accuracy, versatility, and so on. Most disappear from

view immediately, or after a flurry of articles from a single laboratory. Of the successful ones, many have endured, and have been refined gradually, over decades. Here are some new systems that may (or may not) prosper.

''Open sandwich'' (OS) immunoassay could not have been envisaged before recombinant DNA methods had been used to prepare V_H and V_L polypeptides (see Sect. 1.1), because OS assays depend on antigen stabilization of the triple complex V_H–Ag–V_L. When free V_H and V_L were first studied, their association was found to give unstable Fv fragments, and that is why, for applications requiring minimal antibodies, single-chain sFv fragments, in which the two variable polypeptides are joined by a linker peptide, are always used. In contrast, Hiroshi Ueda found, in experiments with a surface plasmon resonance biosensor, that the strength of the interaction between V_H and V_L increases greatly when specific antigen is bound also. From this realization, he went on to devise a range of potentially promising one-site ''sandwich'' immunoassays, and separation-free assays involving fluorescence resonance energy transfer (FRET) or bioluminescence resonance energy transfer (BRET).

Colin Self is best known as the inventor of amplified enzyme assays and their application to the development of ultrasensitive immunoassays, but he has been long aware of the basic limitations of competitive immunoassays, which are the only standard immunoassays suitable for small molecular weight (<1000 g mol^{-1}) ''hapten'' analytes. As summarized recently by Ashton, he has devised and patented a number of sophisticated reagent-excess immunoassay systems for small analytes. The ''selective antibody system,'' involves a blocking molecule (BM) for free sites on the immobilized primary antibody (sp-Ab, sp-Ab–BM) and a labeled anti-idiotypic antibody (aiAb-L) that is added later and binds specifically to the occupied binding site of the primary antibody (sp-Ab–**Ha**, sp-Ab–**Ha**–aiAb-L) (an anti-idiotypic antibody is an antibody that binds to the variable region of another monoclonal antibody.) In this case, because of the role of the ''blocker,'' the anti-idiotypic antibody does not have to be specific for the *occupied* site. Note that, unlike a competitive assay, the complex measured at the end of the assay *does* contain the analyte.

Colin Self's later ''apposition system'' is similar to the above but does not require the difficult task of raising a suitable anti-idiotypic antibody for *every* single primary antibody used. Rather, the challenge is to link, to an appropriate residue near the binding site of the primary antibody, a ligand to which a labeled binding protein can bind. Again, a blocking molecule is used to block all empty binding sites. In principle, the same ligand can be linked to all primary antibodies to be used in a range of assays (perhaps via a suitably located cysteine sulphydryl group inserted in the peptide sequence by ''site-selective mutation'' of the gene coding for the V_H or V_L), making the labeled binding protein a ''universal reagent.''

7 The Limitations of Immunoassays

Absolute specificity that depends on a binding reaction alone is unattainable. Whether the binding protein is an antibody, a hormone receptor or a lectin, the existence of significant concentrations of cross-reacting molecules in (unrefined) samples is a continuous possibility. After

all, the science of pharmacology depends largely on finding or devising substances that strongly cross-react with ''specific'' binding sites.

With hapten analytes, a structurally similar cross-reactant may be able to bind to the specific paratope in a slightly different orientation, or a molecule with a single different functional group may bind because of the existence of a sufficiently large ''pocket'' in the binding site. There is also the well-accepted fact that changes at, or near, the site via which the hapten was conjugated to the immunogen carrier molecule often have little effect on affinity. ''Dissimilar'' cross-reactants, perhaps defined as such by crude comparisons of chemical formulae, are also always possible.

Large protein, glycoprotein or complex carbohydrate antigens interact with a large area of the paratope, thereby making effective epitope uniqueness more feasible. Nevertheless, cross-reacting molecules do occur and, in addition, the achievement of adequate specificity may be exacerbated by analyte heterogeneity. Two-site assays require the recognition of two spatially distinct epitopes and can be exploited to improve specificity when analytes are large, but then there are *two* interactions that are susceptible to general interference instead of one. In contrast, absolute specificity may not always be desirable. For example, as protein analytes are subject to genetic variation, subpopulations of individuals, from whom samples to be analyzed are obtained, may exist that express a variant epitope that is not recognized by a reagent antibody (see Sect. 2.1).

When the analyte is a complex biomolecule, standardization may be especially difficult to achieve because suitable primary standards and ''gold-standard'' reference analytical methods are unavailable. Lately, it has become possible to prepare by recombinant DNA methods primary standards for some complex analytes such as hCG and human kallikrein 2. Reference methods for such analytes also require epitope mapping of the analyte, well-characterized antibodies, and international collaboration to ensure their acceptance and use.

When the analytes are specific antibodies, the required specificity may be quite different from one application to another. The purity and suitability of the antigen reagent is critical and, when class (or subclass) specificity is also required, a two-site design is normally used, so that the specificity of the class-specific antibody used is also vital. In all these designs, antibodies against other antigens or polyspecific antibodies may be detected, and may even give rise to false-positive diagnoses.

However, perhaps no analytical method can be guaranteed in advance to be absolutely specific 100% of the time when the samples to be analyzed are complex and of variable composition. For some types of analyte, isotope dilution mass spectrometry (ID-MS) is used as the ''gold standard'' and this performs as well as it does because it involves at least two stages, one to separate the analyte from the general constituents of its sample matrix and one to measure it. Therefore, when the analyte is presented eventually to the mass spectrometer, it has been extensively purified by means of a high-resolution chromatographic method. In contrast, most immunoassay methods are expected to be accurate and precise when presented with untreated samples. The only preliminary treatment that is accepted as practicable in most situations is dilution.

Therefore, any really effective answer to interference and cross-reactivity as they may affect immunoassays must

also involve preliminary purification of samples. Otherwise the accuracy of every result is completely dependent on the care taken in developing and operating the test. It depends on the careful selection and purity of antibodies (and/or antigens) and other reagents used, on the careful optimization, thorough analytical and biological validation of the assay, and on thorough quality control procedures.

Keywords

Adaptive Immune Response
In contrast to the innate or inborn immune response, the adaptive or acquired immune response is the response of antigen-specific lymphocytes to antigen and is generated by clonal expansion of lymphocytes.

Affinity Maturation
A process during the humoral immune response, which selects for survival of B cells with high affinity for their antigen, which becomes particularly apparent during secondary and subsequent immunizations.

Antigen
Any substance that stimulates the production of antibodies, hence the name is derived from their ability to *gen*erate *anti*bodies. Here, the term is also used for molecules that are recognized by T cells.

Apoptosis
In contrast to necrosis, which is induced by poisoning or anoxia, apoptosis is a programmed cell death in which the cell activates a specialized cellular process to destroy itself. This cell suicide mechanism enables metazoans to control cell numbers and is characterized by nuclear condensation, nuclear degeneration, and DNA degradation.

Chemokine
Proteins secreted by cells that stimulate the activity of other cells. Chemokines have chemoattractant properties, act as messengers between cells and have a central role in inflammatory processes.

Clusters of Differentiation (CD)
A term that was originally coined to define cell-surface molecules that are recognized by a given set of monoclonal antibodies.

Cytokine
Any of various proteins secreted by cells of the immune system that serve to affect the behavior of other cells.

Cytotoxic T cell (CTL)
CTLs are lymphocytes that can kill other cells and are particularly important for the host defense against intracellular pathogens. Most CTLs are MHC class I restricted CD8+ T cells but MHC class II restricted CD4+ T cells can also kill in some cases.

Dendritic Cells (DCs)
Their name originates from their branched or dendritic morphology. The DCs found in lymphoid tissues are the most potent stimulators of T-cell responses. Follicular DCs present antigen to B cells.

Helper CD4+ T Cell (Th Cells)
Th cells are CD4+ T lymphocytes that can help B cells to make antibodies and have been implicated in the generation of functional effector and memory CD8+ T cells. Depending on their cytokine expression profile helper T cells can be divided into Th1 cells, which produce IFN-γ and Th2 cells, which characteristically produce IL-4 and IL-5.

Homeostasis
A state of sustained equilibrium in which cells maintain stable numbers. In the case of lymphocytes, it refers to maintenance of normal numbers of lymphocytes in a noninfected individual.

Immunity
Ability to resist infections.

Immunoglobulin
General term for proteins that function as antibodies.

Interleukin (IL)
Generic term for cytokines produced by lymphocytes.

Lymphocyte
A lymphocyte is any of a group of white blood cells of crucial importance to the adaptive immune system. The two major subsets of lymphocytes are *thymus-dependent lymphocytes* or *T cells* and *B cells*, which are generated in the bone marrow.

Lymphatic System
A system of lymphoid channels and tissues that drains extracellular fluid from the periphery via the thoracic duct to the blood. It includes lymph nodes, Peyer's patches, and other organized lymphoid organs apart from the spleen, which communicates directly with the blood.

Major Histocompatibility Complex (MHC)
It is the most polymorphic gene clusters in the human genome and is encoded on human chromosome 6 (mouse chromosome 17). MHC molecules are membrane glycoproteins that present peptides to T cells. Other gene products of this region included proteins involved in antigen processing and other aspects of host defense.

Pathogen
Any disease-causing organism, such as a virus, bacterium or fungus.

Plasma Cells
Terminally differentiated B cells that are the main antibody-secreting cells of the body. They are found in the medulla of the lymph nodes, in splenic red pulp, and in the bone marrow.

T-Cell Receptor (TCR)
One of the main characteristics of T cells that distinguishes them from all other lymphocytes. It consists of a disulfide-linked heterodimer of the highly variable α- and β-chains, which form a stable complex with the invariant CD3 chains on the cell surface. T lymphocytes expressing this composition of receptor are referred to as α:β T cells, distinguishing them from a smaller subset of T cells that express an alternative receptor on the cell surface consisting of variable γ- and δ-chains in complex with CD3.

Telomere
The end of a chromosome. This specialized structure is involved in the replication and stability of linear DNA molecules.

Transgene
A gene that is integrated into the germline that is expressed *in vivo*.

Vaccination
Process of inducing an adaptive immune response against a given pathogen by stimulation with a dead or attenuated form of the pathogen.

Immunologic memory provides long-term protection against infectious pathogens and is the basis for all vaccinations. Long-term protection is mediated by specialized antigen-specific cells of the adaptive immune system, memory T- and B cell, as well as plasma cells. In response to an invading pathogen, naïve T cells specific for foreign antigen are primed by dendritic cells, expand and differentiate into effector cells that contribute to the clearance of the infection. After the initial immune response, most expanded T cells die and a small population of long-lived memory cells remains. Memory cells are qualitatively distinct from their antigen-inexperienced precursors since they proliferate and acquire their effector functions more rapidly upon repeat exposure to antigen.

1 Introduction

Immunologic memory, manifested as specific resistance to a second encounter with a pathogen, has been appreciated for more than 2000 years. In his book *The history of the Peleponnesian war*, Thucydides describes how a plague – the true pathogen is unknown – swept through Athens in 431 BCE. Thucydides made several observations on the plague including the fact

that those who survived an infection were "*never attacked twice-never at least fatally*." In other words, the few individuals surviving a first episode of plague did not develop disease when similar epidemics recurred.

Although many similar examples of immunity following survival of infection were appreciated over the millennia, intentional exploitation of the mammalian immune system to prevent disease is a relatively recent activity. Between 1718 and 1721, Lady Mary Wortley Montagu, the wife of the British Ambassador to Constantinople, described in her letters a local practice among the Turks for the prevention of smallpox. Turkish women infected healthy individuals intravenously with a small inoculum of matter collected from smallpox lesions, which caused a mild form of the disease, but rendered the person immune to severe smallpox. Almost 80 years later, in 1796, the British physician Edward Jenner reported successful protection of humans against smallpox infection by vaccination with cowpox virus. Vaccination, a term derived from vacca (Latin for cow), became widespread upon confirmation of Jenner's results.

Nearly a century later, Louis Pasteur, while attempting to demonstrate the bacterial cause of chicken cholera, discovered that bacteria grown in culture lose their virulence but maintain the ability to elicit protective immunity. His discovery that chickens immunized with attenuated bacteria developed only mild disease but became resistant to infection with fully virulent bacteria of the same species validated Jenner's concept of immunization. Thus, in the late-nineteenth century, immunization with attenuated vaccines was developed for a number of diseases and applied in Europe and America.

However, many vaccines, particularly those focusing on syphilis, tuberculosis, and salmonellosis, were unsuccessful. Neither Pasteur nor Robert Koch, who outlined the parameters required to characterize an infectious disease, could explain mechanisms of infectious disease and immune defense. Groundbreaking work by Emil von Behring and Shibasaburo Kitasato led to the discovery of antibodies, opening the field of "humoral" immunity. Serum transfer from animals infected with diphtheria into healthy animals and subsequent infection with the pathogen made them resistant to the normally lethal inoculum. This method of conferring "passive immunity" provided the first real opportunity to define immune mechanisms. The nature of the antitoxin antibody was recognized by von Behring and Kitasato to be diphtheria-specific since it could not confer protection to any other disease.

The intense focus on serum-mediated immunity relegated the demonstration by Metchnikoff of cell-mediated antimicrobial defense to a back burner, and it took many decades for this aspect of protective immunity to gain a position at center stage. Indeed, a series of seminal papers by James Murphy, including experiments that demonstrated the "role of lymphoid tissue in the resistance to experimental tuberculosis in mice," remained widely unrecognized. Not until the 1940s did Peter Medawar and Thomas Gibson redirect attention to cell-mediated inflammatory processes. Medawar and Gibson observed that skin graft rejection correlates with cellular infiltration. The pioneering experiments performed by Karl Landsteiner and Merrill Chase showed that resistance to tuberculosis could be established by passive transfer of mononuclear cells. Additional studies by

Mackaness and colleagues demonstrated the critical role of cellular immunity in certain bacterial infections. Subsequently, James Gowans demonstrated that adaptive immunity is mediated by recirculating, long-lived lymphocytes. The thymic origin of these lymphocytes, which were therefore termed T cells, was recognized, and it was shown that they play a central role in mediating resistance to intracellular pathogens. The role of CD4+ and CD8+ T-lymphocyte subsets in adoptive protection against intracellular infection was elucidated shortly thereafter. Both CD4+ and CD8+ T cells provide long-term protective immunity against infections, and much has been learned in the last decade about T cell–mediated immunity. This article will review our current understanding of immunologic memory, focusing on more recent advances.

2 Characteristics of Memory Cells

Memory T- and B-lymphocytes mediate long-term protective immunity to infectious pathogens. A characteristic feature of memory cells is their long-term survival in the absence of reexposure to the pathogen. Additional characteristics of memory T cells are their increased frequency and enhanced responsiveness to antigen. Thus, upon reexposure to antigen following secondary infection, memory cells expand more rapidly and vigorously and acquire effector functions faster than naïve T cells. Indeed, lower concentrations of antigen and less costimulation are required for memory T cell–activation. The physiologic basis for these hallmarks of immune memory has become clearer over recent years.

3 CD8+ T-Cell Memory

3.1 Phenotyping Memory CD8+ T Cells

Memory T-cell subsets are commonly distinguished from naïve cells on the basis of surface marker expression. A number of surface molecules associated with memory and naïve CD8+ T cells are involved in cell adhesion and chemotaxis, consistent with distinct trafficking of different T-cell populations. During a primary immune response, IL-7Rα (CD127) is downregulated on most CD8+ T cells and only a small subset of cells continues to express this marker during the effector phase. Only those cells that are $CD127^{hi}$ survive and contribute to the pool of memory cells. Hence, CD127 is a marker for precursor cells that are destined to become memory cells. The expression of the adhesion molecules CD44 and CD62L has been applied to define memory cells. While naive cells are $CD44^{lo}$ and $CD62L^{hi}$, they become $CD44^{hi}$ and $CD62L^{lo}$ upon activation. To make matters more complicated, however, CD62L is reexpressed on a fraction of memory cells, and expression of CD44 varies among different mouse strains. Recent studies have demonstrated that memory CD8+ T cells can be divided into effector memory ($CD62L^{low}$ $CCR7^{-}$) and central memory ($CD62L^{hi}$ $CCR7^{+}$) populations, on the basis of L-selectin (CD62L) and the CC-chemokine receptor 7 (CCR7) expression.

The expression of tyrosine phosphatase CD45 isoforms is also used to distinguish between T-cell differentiation stages. The CD45RB isoform is generally detected on naive cells while memory cells express the CD45RA and CD45RO isoforms. However, because CD45 isoform expression

on memory versus naïve T cells is complex and can change with nonspecific activation and cytokine treatment, CD45 is a relatively unreliable marker for memory T-cell definition.

The IL-2 receptor α-chain (CD25) and CD69 are rapidly expressed by T cells upon encountering cognate antigen, but their expression is not sustained on memory T cells. Similarly, O-glycosylation on mucin-type surface glycoproteins such as CD43 can distinguish effector from memory cells. Some memory T cells, however, express the IL-2 receptor β-chain (CD122), a component common to both IL-2 and IL-15 receptors, the latter cytokine being essential for memory CD8+ T-cell maintenance. Ly-6C has also been used as a marker to distinguish effector from memory T cells. Low and intermediate expression of this marker is characteristic of effector T cells, while it is highly expressed on memory T cells.

More recently, classification of human virus-specific T cells into naïve, effector, and memory cells on the basis of CD27 and CD28 expression was described. Human immunodeficiency virus (HIV), Epstein–Barr virus (EBV), cytomegalovirus (CMV) and hepatitis C virus (HCV) specific T cells, while similar during primary infection, give rise to distinct memory T-cell populations during chronic infection, which are characterized by differential expression of various surface antigens and effector molecules. Naïve CD8+ T cells are CD27+ CD28+ and express CCR7. Early and intermediate effector T cells downregulate CD28, CCR7, and CD45RA and express cytotoxic factors such as perforin, granzyme A, and GMP-17 (a marker for cytotoxic granules and lysosomes). Memory cells appear to lose the CD28, CD27, and CCR7 markers and maintain CD45 expression at low levels. They exhibit a greater cytotoxic potential than nonprimed cells and their telomeres are shortened. In this study, T-cell populations responding to persistent viral infections were more diverse than expected. EBV and HCV promoted the development of early effector memory T cells while HIV induced intermediate and CMV induced terminally differentiated memory T cells. In aggregate, recent studies demonstrate the remarkable diversity within memory T-cell populations and illustrate the importance of integrating phenotypic and functional characteristics when assessing memory T cells.

3.2 Enhanced Responsiveness of Memory CD8+ T Cells: Potential Mechanisms

Enhanced sensitivity of memory T cells for cognate antigen likely results at least in part from more rapid signal transduction. Priming of naïve T cells leads to association of the tyrosine kinase Lck with the CD8 coreceptor, thereby enhancing TCR signaling. The association between Lck and CD8 is maintained in memory cells, which contributes to the lower stringency for activation of effector and memory cells. PEST domain-enriched tyrosine phosphatase (PEP) has recently been implicated as a negative regulator for specific aspects of T-cell development and function. Mice deficient in PEP demonstrate enhanced activation of Lck, which results in increased expansion and function of the effector and memory T-cell pool. Additional qualitative differences have been reported further downstream in the signaling cascade, involving the mitogen-activated protein (MAP) kinases ERK1 and 2 (extracellular signal-regulated

kinase), which activate transcription factors essential for T-cell activation. In contrast to naïve T cells, memory cells show an increased ability to phosphorylate ERK1 and ERK2, thereby accelerating signal propagation.

In addition to enhancing the rate of T-cell activation, regulation of signaling molecules can also influence activation-induced differentiation of memory cells. For example, transgenic mice expressing a partially calcium-independent mutant of the calcium/calmodulin kinase II (CaMKII) γB show an increase in the number of T cells in secondary lymphoid organs with a memory phenotype suggesting that this kinase is important for the development of memory.

The stage of the cell cycle that most naïve and antigen experienced T cells occupy also differs. Naïve T cells are arrested in the G0/G1 stage, with high expression of the cyclin dependent kinase (CDK) inhibitor p27Kip1 and low activity of the CDK6 and CDK2. In contrast, memory CD8+ T cells are also in G0/G1 but have low expression of p27Kip1 and high CDK6 kinase activity. This results in a preactivated cell cycle state of memory T cells that favors rapid division after antigen stimulation.

Lymphocyte differentiation is associated with programmed alterations in gene expression, which is largely regulated by structural changes in chromatin. Distinct gene expression profiles have been reported for memory cells. For example, mRNA levels for several cytokines including RANTES, interferon-γ (IFN-γ), and cytotoxic molecules such as perforin and granzyme B are elevated in memory T cells. Transcripts for these genes are rapidly translated in memory T cells following TCR stimulation, circumventing the time required for transcriptional activation.

3.3 Generation of Memory CD8+ T Cells

At the end of an immune response to an invading pathogen, most of the clonally expanded T cells die, leaving a small population of memory T cells, which is maintained for long periods of time. How do memory T cell–precursors survive during the contraction phase of the immune response and which cells become long-lived memory cells? Recent experiments revealed that the homotypic form of CD8, CD8$\alpha\alpha$, is selectively expressed by CD8+ memory T cell–precursors and is required for their survival. Mice that are deficient in the CD8 enhancer ($E8_I$) express the usual heterotypic CD8$\alpha\beta$ molecule but not the homotypic form CD8$\alpha\alpha$. $E8_I$ knock-out mice mount a normal primary immune response but show diminished memory expansion. CD8$\alpha\alpha$ interacts with the non-classical MHC class I like molecule, thymic leukemia (TL) antigen. This interaction has been shown to modulate T-cell responses and leads to enhanced expression of IL-2/IL-15Rβ and IL-7Rα. CD8+ memory T-cell precursors express IL-7Rα chain, which renders them responsive to cytokine mediated survival signals. IL-7 is a potent survival factor for both naïve and memory CD8+ T cells due to the induction of antiapoptotic factors such as Bcl-2 and Bcl-X_L.

Studies of CD8+ T-cell memory have been greatly facilitated by the increasing spectrum of mice with targeted genetic deletions. For example, mice deficient in CD27, a member of the TRAF-linked tumor necrosis factor (TNF) receptor family that plays a costimulatory role during T-cell priming, have a markedly diminished virus-specific memory CD8+ T-cell response. On the other hand, mice lacking the CD28 costimulatory molecule, while

deprived of CD86-mediated helper signals, mount nearly normal memory CD8+ T-cell responses in response to lymphocytic choriomeningitis virus (LCMV) or *Listeria monocytogenes* infection, supporting the notion that the costimulatory networks contain built-in redundancies that can compensate for the absence of CD28. However, costimulatory requirements for memory T-cell generation can vary significantly, since different pathogens create distinct inflammatory milieus. For example, induction of long-term immunity to influenza virus infection in contrast to LCMV and *L. monocytogenes* infection, requires CD28 signaling. 4-1BB, a TNF receptor family member, is another costimulatory molecule that has an impact on memory T-cell formation. Mice lacking 4-1BB ligand have diminished late expansion of virus-specific effector and memory CD8+ T cells, suggesting that 4-1BB signals play a role in sustaining T-cell activation and memory generation.

TNFR-associated factor 2 (TRAF2) is an adapter protein, which associates with the cytoplasmic tail of several TNF receptor family members including CD27, CD40, OX40, and 4-1BB and thereby links signals to downstream pathways. Hence, the absence of TRAF2 is likely to abrogate signaling through multiple costimulatory pathways. However, studies using dominant negative forms of TRAF2 demonstrated that in response to influenza virus infection, only secondary CD4+ and CD8+ T-cell expansion is decreased, while the primary expansion is not affected.

Cytokines are also implicated in the generation of antigen-specific memory T cells. Infection of IL-15- or IL-15Rα-deficient mice with LCMV generates a potent primary response but the memory pool decreases gradually over time, leading to impaired secondary CD8+ T-cell expansion. This demonstrates differential IL-15 requirements for naïve and memory CD8+ T cells. In the absence of IL-15 signaling, the memory response is also diminished following vesicular stomatitis virus (VSV) infection; however, the primary CD8+ T-cell expansion also appeared to be impaired. These studies suggest that in some circumstances, IL-15 may play a role in the generation of memory CD8 T cells.

CD4+ T cells have also been implicated in the generation of CD8+ T-cell memory; however, their importance varies with the type of infection. In the setting of LCMV infection, CD4+ T cells are not necessary for primary CD8+ T-cell responses, but they are indispensable for long-term CD8+ T-cell memory. Remarkably, CD4+ T cells contribute to CD8+ T-cell memory at the time of initial priming, since activation of memory CD8+ T cells occurs independently of CD4+ T-cell help. In contrast to viral infections, generation of memory CD8+ T cells during bacterial infections appeared to be less dependent on CD4+ T cells. For example, although mice lacking the class II transactivator (CIITA) have diminished numbers of CD4+ T cells, they generate memory CD8+ T cells following infection with the *L. monocytogenes*. Consistent with this result, CD4+ T cell-depleted, CD4−/−, and MHC class II−/− mice immunized with *L. monocytogenes* 3 to 4 weeks prior to rechallenge, mount protective recall responses. However, the consequences of the lack of CD4+ T cells help in generating functional CD8+ T-cell memory become more apparent many months following the initial antigen encounter. Recent data demonstrated that memory CD8+ T cells generated without CD4 help are defective in their ability to respond to secondary encounters with antigen. Memory CD8+

T-cell generation seems to be dependent on the presence of Th cells during, but not after, priming, suggesting that T-cell help is ''programmed'' into CD8+ T cells during priming. However, this concept was challenged by studies in which memory CD8+ T cells were adoptively transferred into wild type or CD4+ T cell-deficient recipients. The presence of CD4+ T cells was only important after, but not during, the early CD8+ T-cell programming phase, suggesting that CD4+ T cells are required only during the maintenance phase of long-live memory CD8+ T cells.

An important mechanism by which CD4+ T cells provide help to CD8+ T cell is through CD40-CD154 interactions. Antigen-presenting cells (APCs) were originally thought to be the mediators for these signals. Recent data demonstrates, however, that activated CD8+ T cells that express CD40 may receive direct help for CD4+ T cells expressing CD154. Administration of agonistic anti-CD40 monoclonal antibodies greatly enhances the protective potential of adoptively transferred, *L. monocytogenes*-specific CD8 T cells, providing further support for the role of CD40 in memory T-cell generation and/or maintenance.

Signals transmitted from CD4+ T cells are not uniformly stimulatory. In recent years, CD4+ CD25+ T regulatory cells have been implicated in the control of autoimmunity. During infection with *L. monocytogenes*, CD4+ CD25+ T regulatory cells can suppress memory CD8+ T-cell expansion. Similar observations were reported for memory CD8+ T-cells responses to infection with herpes simplex virus (HSV). Thus, CD4+ T cells play both positive and negative roles in the control of CD8+ T-cell memory.

Primary infection with *L. monocytogenes* induces memory T cells specific for multiple distinct peptides. CD8+ T cells restricted by the nonclassical MHC class Ib molecule H2-M3 and specific for *N*-formyl methionine peptides expand more rapidly than MHC class Ia-restricted CD8+ T cells during a primary infection. However, the memory responses of H2-M3-versus MHC class Ia-restricted T cells are dramatically different. H2-M3-restricted memory T cells express activation markers upon reencountering antigen, but do not proliferate, while MHC class Ia-restricted T cells undergo explosive expansion. It was initially suggested that this disparity may reflect differences in thymic selection of these two CD8+ T-cell types. However, more recent data show that MHC class Ia-restricted memory T cells inhibit the H2-M3 memory response by rapidly terminating *in vivo* antigen presentation of H2-M3 antigen following secondary infection.

3.4 Maintaining CD8+ T-Cell Memory

Most infections are eliminated by the mammalian host, yet memory T cells persist afterwards for many years. Determining the mechanisms that enable long-term memory T-cell persistence in the absence of antigen has been a great challenge. Pioneering studies with adoptively transferred, antigen-specific memory T cells demonstrated the ability of these cells to survive in MHC-deficient mice. These observations provide strong evidence that once the differentiation program is initiated, memory CD8+ T cells can persist in the absence of antigen. However, immunological T-cell memory that is maintained without MHC contact may become functionally impaired. For example, memory CD4+ T cells specific for the male (HY) antigen show defective responses upon rechallenge and also alter

their surface phenotype expression if they are kept in MHC-deficient hosts.

If maintenance of memory T cells is MHC and antigen independent, what regulates their persistence? Recent studies have demonstrated that IL-15 is crucial for *in vivo* maintenance of memory CD8+ T cells. Both primary and memory CD8+ T-cell expansion is diminished in IL-15- or IL-15-receptor-deficient mice, and maintenance of memory T-cell populations following immunization is markedly attenuated in the absence of IL-15 signaling. The gradual decline in memory CD8+ T-cell numbers in the absence of IL-15 results from decreased proliferation by memory cells. Interestingly, IL-7 can compensate for the missing survival signals in the absence of IL-15. When IL-7 is overexpressed in IL-15−/− mice, memory CD8+ T cells are generated, while removal of IL-7 and IL-15 completely inhibits the homeostatic proliferation of CD8+ memory T cells. These findings emphasize the joint contribution of these two cytokines for promoting CD8+ memory T-cell proliferation. Surprisingly, IL-2, a factor best known for its ability to stimulate T-cell proliferation, appears to play a negative role in memory T-cell survival.

In comparison to effector CD8+ T cells, memory CD8+ T cells express high levels of bcl-2 mRNA and protein, explaining their relative resistance to apoptosis. One effect of IL-15 is to increase bcl-2 levels in memory T cells, providing a second IL-15-mediated mechanism for memory CD8+ T-cell maintenance.

Cap structures that protect telomeres from degradation and terminal fusion play an essential role in stabilizing chromosome ends. Telomeres tend to progressively shorten when cells proliferate, eventually resulting in death of the proliferating cell. Telomere length, however, can be maintained in cells with activated telomerase, which adds DNA to telomeres with each cell division. Naïve as well as memory T cells undergo massive proliferation following antigen encounter. In order to compensate for telomere shortening, telomerase is more active in memory than naïve or effector T cells, potentially contributing to their long-term survival.

3.5 Models of CD8+ T-Cell Memory Generation

While some aspects of memory T-cell maintenance have been characterized, the mechanisms that generate memory CD8+ T cells are less clear. Several models for memory generation have been proposed and are outlined in this section. The recent introduction of methods that precisely quantify antigen-specific T cells during immune responses has provided immunologists with a framework upon which to build these models.

The *linear differentiation model* of memory T-cell formation proposes progressive differentiation of T cells from naïve to effector to memory cells (see Fig. 1). Following initial stimulation, an activation program drives naïve T-cell differentiation into effector cells, followed by further differentiation of a subset of effector T cells into memory T cells. Early support for this model came from TCR repertoire analyses of effector and memory T cells. The TCR repertoire of primary CD8+ T-cell responses is similar to that of memory CD8+ T cells, suggesting that memory cells are stochastically chosen from the population of effector CD8+ T cells activated during the primary infection. While linear differentiation of memory T cells was supported by adoptive transfer studies with T-cell receptor (TCR), transgenic (tg) CD8+ T cells specific for the male H-Y antigen, the most

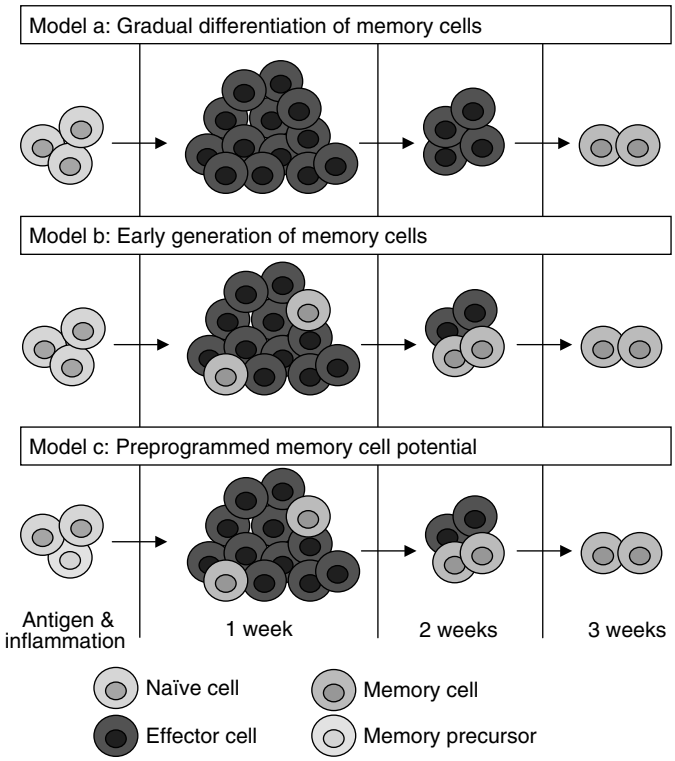

Fig. 1 Models of programmed memory T-cell generation.

direct evidence in support of this model came from studies using a clever system for genetically marking T cells that had acquired effector function. In this study, memory T cells were derived from effector T cells. It also remains controversial when memory cells form during the course of an immune response (see Fig. 1). One recent study demonstrated that T cells require several weeks from the time of antigen encounter to differentiate into memory T cells. Other studies showed that rechallenge of mice with a high inoculum of antigen 5 days after primary immunization resulted in a memory-like CD8+ T-cell response, suggesting that memory T cells may already be present during the primary immune response.

A variation of the linear differentiation model proposes that different memory T-cell subsets develop at different times following T-cell priming. According to this model, primed effector T cells can, in the absence of further stimuli, develop into CCR7+ CD62L+ central memory cells, which home to lymph nodes and lack effector functions. In contrast, effector memory cells, which are CCR7− CD62L−, derive from effector cells that have undergone more prolonged stimulation with antigen. This subset of memory cells produces high levels of effector cytokines, maintains cytolytic activity, and trafficks to peripheral tissues. Some evidence suggests that effector memory cells can convert to central memory cells upon antigen clearance.

Evidence in support of this model comes from the analysis of T-cell priming by live versus killed bacterial vaccines. Live bacteria, which induce substantial inflammation, result in large effector memory T-cell populations, while killed bacteria, which induce an attenuated inflammatory response, give rise to T cells with a central memory phenotype.

Another model for memory T-cell development is the *decreasing-potential model,* which is based on the progressive loss of proliferative capacity. The underlying idea of this model is that successful memory T-cell generation requires a short duration of antigenic exposure during T-cell priming. According to this model, larger numbers of functional memory T cells should be produced when effector T cells are briefly exposed to antigen, thereby avoiding antigen driven apoptosis (AICD). Support for this model comes from situations of overwhelming antigen dose or during chronic infections, such as HIV or hepatitis C, where antigen-specific T cells either disappear or become dysfunctional.

A variant of the decreasing-potential model suggests that the timing of T-cell priming during an immune response determines which cells enter the memory lineage. The circulation of lymphocytes between the blood and lymphatic system is a rather slow process with turnover times of 12 to 24 h. Thus, the time that it takes for individual lymphocytes to encounter antigen presented in secondary lymphoid organs can vary significantly. Since antigen presentation is transient, cells recruited later will encounter antigen for a shorter time period than cells that are initially recruited. Brief exposure to antigen would be sufficient to induce their proliferation and differentiation into effector cells; however, the signal would be inadequate to trigger death pathways. Further studies are required to provide experimental support for this model.

The third model for memory T-cell generation is the *instructive model*, which posits that effector and memory T-cell differentiation diverges during T-cell priming. According to this model, memory T cells directly differentiate from naïve T cells without passing through the effector stage. Although experimental support for this model is sparse, the notion that naïve T cells might take their cues from the inflammatory and costimulatory context and undergo differentiation into either effector or memory T cells remains plausible.

T-cell programming is a relatively new concept that should be incorporated into models of memory T-cell generation (see Fig. 2). Early studies demonstrated that CD8+ T cells specific for different epitopes undergo coordinate expansion

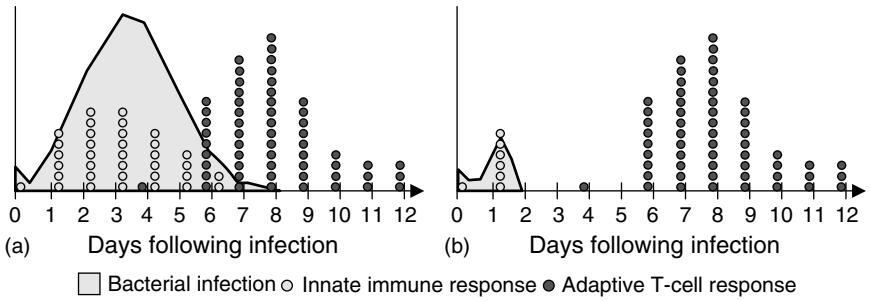

Fig. 2 Antigen-independent proliferation and memory generation.

and contraction in response to infection, despite substantial differences in antigen expression levels and stability of peptide-MHC complexes. One explanation for this finding is the relatively short duration of effective *in vivo* antigen presentation, which results from downregulation by the nascent T-cell response. While feedback inhibition limits T-cell priming to the very early phase of the infection, the brief period of priming is sufficient to initiate a program of antigen-independent T-cell expansion. Remarkably, the process of T-cell expansion, contraction, and memory formation occur in the absence of both antigen and inflammation.

4
CD4+ T-Cell Memory

While CD8+ T-cell memory has been extensively investigated, less is known about the generation and maintenance of memory CD4+ T cells. One explanation for this disparity is the difficulty to directly identify antigen-specific CD4+ T cells during the course of an immune response. One recent study, however, has compared CD4+ and CD8+ memory T-cell responses to LCMV and found that virus-specific memory CD4+ T cells decline in frequency over time while memory CD8+ T cells are maintained at high frequencies. In this section, we will concentrate on recent studies focusing on memory CD4+ T cells.

4.1
Differentiation of Effector and Memory CD4+ T Cells

Naïve CD4+ T cells, upon *in vivo* priming, differentiate into either Th1 or Th2 effector cells. While the mechanisms leading to Th1 or Th2 differentiation remain incompletely understood, the innate inflammatory response elicited by the invading pathogen plays a major role in this process. Many viruses and bacteria induce IL-12 and interferon-γ (IFN-γ) secretion, driving the differentiation of naïve CD4+ T cells into Th1 cells. In contrast, Th2 immunity, which is induced by intestinal helminth infection, is associated with innate inflammatory responses that produce IL-4, driving naïve CD4+ T-cell differentiation into Th2 cells. While the Th1/Th2 lineage decision has important consequences for the primary immune response, long-term memory T cells maintain the phenotype induced at the time of priming. Thus, while memory CD4 T cells do not produce cytokines in the absence of stimulation, upon reencountering antigen they rapidly reexpress the cytokines elicited during their primary activation. Several studies have demonstrated that epigenetic chromatin remodeling during the primary T-cell response accounts for specific cytokine expression profiles of reactivated memory T cells.

4.2
Phenotype of Memory CD4+ T Cells

Memory CD4+ T cells have a lower threshold for activation than naïve T cells. Indeed, memory CD4+ T cells respond more rapidly to antigen, with enhanced cytokine secretion and greater proliferation in response to low antigen doses. In addition to greater responsiveness to antigen, memory CD4+ T cells are also present at higher frequencies in immune animals. While cytokine production by naïve CD4+ T cells is restricted to IL-2 and IL-3, memory CD4+ T cells secrete a

greater variety of cytokines. Adoptive transfer of *in vitro* generated antigen-specific Th1 and Th2 cells leads to long-lived memory cells, which produce a pattern of cytokines closely related to that of the originally transferred cells. As mentioned in the previous section, epigenetic imprinting accounts for the fidelity of memory T-cell cytokine production.

4.3 Memory Generation and Maintenance

Mechanisms for CD4+ memory T-cell generation have not been defined. While models similar to those outlined for CD8+ T-cell memory formation may be applicable to CD4+ T-cell memory generation, existing data most strongly support linear differentiation from naïve to effector to memory CD4+ T cells. *In vitro* studies, for example, demonstrated that effector CD4+ T cells can differentiate into memory cells without the requirement for cell division. However, the factors involved in the transition from effector to memory T cells remain unclear. Remarkably, CD4+ T-cell memory is efficiently generated in the absence of IL-2, IL-4, or IFN-γ. As with CD8+ T cells, initial antigen stimulation is sufficient to initiate programmed expansion in CD4+ T cells, and extended antigenic stimulation is not required for differentiation into memory cells or for long-term persistence. Indeed, memory CD4+ T cells persist in the absence of both antigen and MHC class II molecules.

The cytokine requirements for long-term memory CD4+ T-cell survival are distinct from those described for memory CD8+ T cells. For example, while memory CD8+ T cells decrease in frequency in the absence of IL-15, memory CD4+ T cells are maintained independently of IL-15. Consistent with this finding, CD122 is expressed at low levels on memory CD4+ T cells. In addition, memory CD4+ T cells undergo homeostatic proliferation in the absence of both IL-7 and IL-15, and CD4+ T cells from mice deficient in the common cytokine receptor γ–chain, which is shared by receptors for IL-2, -4, -7, -9, and 15, can generate long-lived CD4+ memory T cells. IL-7 might not be essential for the homeostasis of CD4+ memory T cells, but contributes to the maintenance of all naïve and memory T-cell subsets, and thereby influences the control of the overall size of the T-cell pool. Differences in CD8+ and CD4+ T cell–memory maintenance have been detected following viral infection: virus-specific CD4+ memory T cells gradually decline, while CD8+ memory T cells remain stable. While many factors have been excluded as essential to CD4+ T cell–memory formation, the underlying mechanisms that drive differentiation of effector into memory T cells remains mysterious.

4.4 Trafficking of Memory CD4+ T Cells

CD8+ as well as CD4+ T cells differentiate in memory subsets with distinct effector functions and migration capacities. The differences in homing and trafficking of CD4+ T cells can be attributed to their expression of the selectin CD62L and the chemokine receptor CCR7. Central memory (CCR7+, CD62L+) CD4+ T cells are preferentially home to lymphoid tissues, whereas effector memory (CCR7−, CD62L−) recirculate in peripheral tissues long after immunization. The localization of central and effector memory CD4+ T cells in different organs has been directly visualized by immunohistology on whole body sections.

5
B-Cell Memory

5.1
Generation of B-Cell Memory

Similar to memory-T cells, memory-B cells respond rapidly to secondary exposure to antigen, proliferating and producing high affinity antibodies. B cells require accessory signals provided by helper T cells for full differentiation and are also activated by certain microbial stimuli. There are two distinct developmental pathways for antigen-specific B cells. B-1 and marginal-zone B cells proliferate and differentiate into antibody-secreting plasma cells, thereby providing the most rapid humoral response to antigen. While many plasma cells have a life span limited to a few days or weeks, some develop into long-lived cells that mediate long-term humoral immunity. Some antigen activated B cells migrate into follicles where they proliferate and form germinal centers (GCs), an important site of antibody secretion and affinity maturation. B cells expressing high affinity immunoglobulins receive positive signals from T-helper cells, leading to B-cell proliferation, survival, and maturation.

Lymphotoxin (LT) is important for development of peripheral lymphoid organs since mice lacking lymphotoxin-α (LT-α) receptor have no lymph nodes or Peyer's patches and fail to form germinal centers. These structural deficits are linked to defective isotype-switching following primary or secondary immunization with T cell–dependent antigens. The important role of germinal centers in memory B-cell formation was demonstrated in adoptive transfer experiments. B cells from LT-$\alpha-/-$ donors were capable of giving rise to a memory population, whereas a memory IgG B-cell responses could not be elicited in LT-$\alpha-/-$ hosts. These studies clearly support previous observations, which point out the important role of germinal center structures for memory B-cell development.

Some of the factors determining the lineage decision between plasma cells and memory B cells have been identified, and include cell-surface receptors, cytokines, and transcriptional regulators. Stimulation through CD40-CD154, IL-4, expression of PAX5 and BCL-6 inhibit plasma cell differentiation. On the other hand, absence of CD40, IL-3, IL-6, and IL-10 and the commensurate degradation of BCL-6 and induction of Blimp-1 (B-lymphocyte-induced maturation protein 1) promote plasma cell differentiation.

CD4+ T cells are crucial for the generation of long-term humoral immunity. Direct antigen-specific T-B-cell interactions have been visualized with adoptive transfer systems, and the molecular requirements for CD4+ T-cell help have been identified recently. One important participant in this process is the signaling lymphocyte activation molecule (SLAM), SLAM-associated protein (SAP), which was originally identified as altered in X-linked lymphoproliferative syndrome (XLP). SAP controls signaling via the family of SLAM surface receptors, including CD84, CD150 (SLAM), CD229, and CD244 and hence plays a fundamental role in T-cell function. Mice deficient in the SAP gene (SAP$-/-$) mount strong antibody responses during an acute viral infection, but they fail to generate long-lived virus-specific plasma and memory-B cells. Adoptive transfer experiments demonstrated that SAP expression by CD4+ T cells, but not B cells, is

essential for generation of long-term humoral immunity.

5.2 Maintenance of B-Cell Memory

It has been proposed that long-term humoral immunity is maintained by memory B cells, which continuously differentiate into short-lived plasma cells. Recently, however, it was shown that long-lived plasma cells survive for prolonged periods of time and maintain humoral immunity in the absence of memory B cells. Maintenance of humoral immunity appears to be antigen independent since memory B cells persist in the absence of antigen. Some experiments support the hypothesis that survival of long-lived plasma cells is determined by microenvironment rather than by intrinsic factors. *In vitro* experiments, for example, show that plasma cells isolated from tonsils undergo apoptosis unless rescued by stromal cells. Further support for this concept comes from the observation that plasma cell maintenance is restricted by the capacity of the splenic red pulp to provide ''space,'' suggesting that plasma cell homeostasis is regulated by competition for specific survival niches.

Nerve growth factor (NGF) regulates neuronal cell development and survival. The finding that patients with autoimmune disorders often have elevated NGF plasma levels, and that NGF receptor shares structural similarities with some cytokine receptors suggested a role for this cytokine in the immune system. B cells can produce NGF under basal conditions and constitutively express NGF-receptors. It turns out that NGF acts as an autocrine survival factor for memory B cells and its neutralization completely inhibits humoral memory responses.

6 Conclusions

The journey to decipher memory T- and B-cell development continues to be a great scientific adventure, and there remain many unanswered questions that will require additional clever models and experiments. The motivation for moving forward, however, is substantial. Delineating basic mechanisms is important and applying the knowledge gained from an enhanced understanding of immunologic memory to the development of vaccines, against both infectious diseases and malignancy, will be especially satisfying.

Keywords

Antigen-presenting Cells (APC)
Cells such as dendritic cells or macrophages that are capable of presenting peptide antigens to T cells for immune recognition and activation.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 6
Edited by Robert A. Meyers.

ISBN: 3-527-30548-3

B-cell Receptor (BCR)
The surface immunoglobulin expressed on the surface of each B cell that uniquely recognizes an antigenic determinant.

Cluster Determinant (CD)
An internationally recognized nomenclature that identifies and classifies cell surface antigens on leukocytes that are recognized by monoclonal antibodies

Cytotoxic T Cells (CTL)
T lymphocytes that are capable of killing target cells, either antigen-specific or polyclonal.

Major Histocompatibility Complex (MHC)
In humans, referred to as human leukocyte antigen (HLA).

Monoclonal Antibodies (mAb)
Antibodies captured by cell fusion technology or recombinant DNA techniques that are produced in large quantities for diagnostic and therapeutic use.

Natural Killer (NK) Cells
Cells of the hematopoietic system that are neither lymphocytes nor classical myeloid cells that are capable of mediating cytotoxicity against a variety of tumor cells.

T-cell Receptor (TCR)
A dimeric cell surface protein on the surface of T cells that recognizes antigens expressed on antigen-presenting cells.

Tumor-associated Antigens (TAA)
Antigens uniquely expressed or overexpressed on tumor cells.

Cancer or tumor immunology refers to the field of study that seeks to define the role of the immune system in controlling and regulating the growth and survival of malignant cells. From animal studies, it has been known for decades that tumor cells can be recognized and eliminated by the immune system. The basis of immune recognition is the expression of tumor-associated or tumor-specific molecules by tumor cells in a manner that is recognizable to the various components of the immune system. Much has been learned about the antigens, antigen-presenting cells, and effector cells of the immune system over the past several years. This is still a discipline in its infancy, which is yet to fulfill the dream of effective control of human tumors by natural immunological processes. This chapter will review the current state of the science and the prospects of meaningful application of the immune system to human disease.

1
Tumor Antigens

The fundamental notion of tumor immunology is that the host immune system has the capacity to recognize antigens on tumor cell surfaces that are different from normal antigens, to which immune tolerance has already developed. The evidence for the existence of tumor antigens comes from decades of study in animal models. For example, classical experiments in the 1950s demonstrated that animals "immunized" with irradiated syngeneic tumor cells protected the host from subsequent challenge with viable tumor cells.

The molecular basis of tumor-associated antigens (TAA) has been elucidated in recent years, in concert with an unraveling of the mechanism by which antigens are perceived by the immune system. It is now known that polypeptide antigens are processed and presented as small peptides in the groove of class I and II HLA molecules and thus recognized by specific T cells through the T-cell receptor (TCR).

There are several mechanisms by which tumor antigens may arise (Table 1). It is increasingly clear that cancer is a genetic disease, resulting from various mutagenic events in the DNA of the subject. TAA may be generated through mutations in the genome of the cancer cell mediated by carcinogenic chemicals, leading to the generation of new protein molecules that are different from normal self-antigens. Point mutations, chromosomal translocations resulting in fusion genes and their encoded molecules, breaks in DNA strands, and numerous other molecular changes in DNA lead to altered protein structures in cancer cells.

Other candidates for tumor antigens include tissue-specific antigens that are overexpressed on tumor cells as a consequence of the neoplastic transformation. It would not be expected that these "normal" self-antigens would generate an immune response. However, as we will discuss below, these overexpressed antigens may be targets for targeted immunotherapy with monoclonal antibodies or cellular effectors.

Tab. 1 Tumor-associated antigens.

Origin of TAA
• Chemical mutagenesis
• Spontaneous mutation with mismatch repair defects
• Viral mutagenesis
• Chromosomal translocations (bcr-abl, AML/ETO1)
• Altered glycosylation (MUC-1)
• Idiotypic epitopes on B-cell malignancy (CLL, NHL, MM)
• Overexpression of normal tissue-specific antigens on transformed tissue
Classes of tumor-associated antigens
• Cancer testis antigens
• Differentiation antigens
• Viral antigens
• Mutated tumor suppressor antigens
• Oncogene products
• Unique antigens

Tumor antigens in human solid tumors were first described in malignant melanoma and prostate carcinoma. Through the creation of cytotoxic T-lymphocyte cell lines from patients with malignant melanoma, antigens such as MAGE-1, MART-1/Melan-A and NY-ESO-1 were found to be expressed on cells from these cancers. These peptide antigens are also expressed on normal testis tissue, leading to the classification of such antigens as ''cancer testis antigens.'' Since then, literally hundreds of peptide antigens and their HLA restricting alleles (both class I and II) have been described through similar techniques. Recently employed technologies including microarray, subtractive hybridization, and representational-difference analysis have revealed many more candidate human TAA.

Despite the theoretical and demonstrated existence of tumor antigens in human tumors, clearly the immune system in man is quite ineffectual in recognizing these antigens since cancer continues to spontaneously emerge at an alarming frequency. This sobering fact leads to the conclusion that tumor cells may be immunosuppressive to the immune system, poor ''presenters'' of their altered self-antigens, or that they can elude the immune system by other mechanisms such as continuous mutation or rapid growth kinetics. There are also examples of humoral (antibody) responses to TAA. In this instance, a cell surface or circulating antigen is recognized by the B-cell antigen receptor (BCR) leading to its internalization, induction of antibody synthesis, and processing of the antigen for expression by class II HLA molecules and subsequent presentation to $CD4^+$ T cells. Thus, both a cellular and humoral response may be generated to the same TAA.

2 Antigen Presentation

The immune system has evolved with 2 major arms, the innate arm and the adaptive arm. Innate immunity recognizes nonself-antigens in a nonspecific fashion. Each time a similar antigen is encountered, a similar response pattern is initiated. No memory component is involved. Components of the adaptive system are also activated as a result. Macrophages, interdigitating dendritic cells, and natural killer (NK) cells are important cellular components of the innate immune system. Various cytokines, complement and acute phase proteins also play key roles.

The adaptive immune system includes both humoral and cellular arms. It responds primarily to exogenous antigens that are first processed by cells, and then presented in the context of self-HLA to specialized receptors on B and T lymphocytes. Many animal and human studies support the concept that the cellular arm has a greater role in both tumor surveillance and tumor-directed immune responses. Observations include the efficacy of high doses of interleukin-2 (IL-2) in some patients with malignant melanoma and renal cell cancer and also studies demonstrating that rejection of transplantable tumors was mediated primarily by components of the cellular immune system.

For a TAA to induce an effective cellular immune response, antigen has to be presented directly or via an antigen-presenting cell (APC) to a lymphocyte bearing a T-cell receptor (TCR) that recognizes epitopes on the presented antigen. Cross linking of the TCR can then occur but additional cell–cell interactions are critical for T-cell activation. These involve essential costimulatory molecules as shown in Fig. 1. If, following

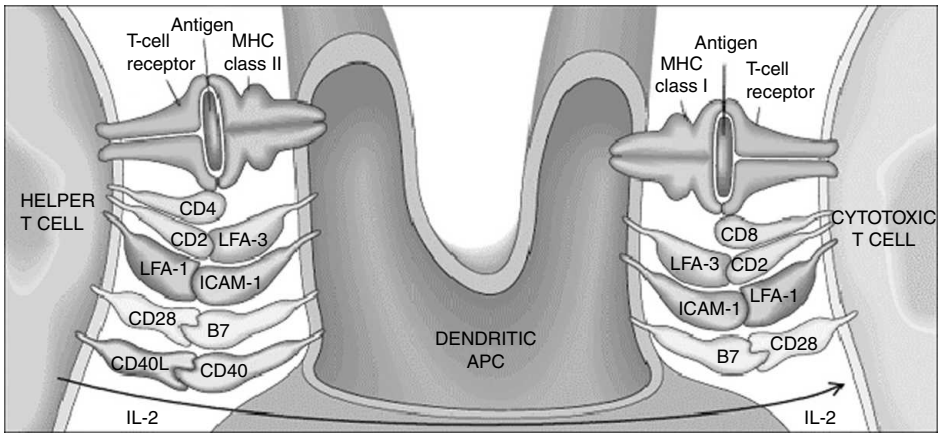

Fig. 1 Antigen presentation by APC through class I and II HLA. Helper T cells recognize MHC class II-associated antigens. Cytotoxic T cells recognize MHC class I-associated antigens. Release of interleukin-2 (IL-2) by the helper T cell provides a so-called help signal to the cytotoxic T cells. (ICAM-intercellular adhesion molecule; LFA-leukocyte function–associated antigen). Redman, D.O., Section 12, Oncology, and Section 6, Immunology/Allergy, published in ACP Medicine, edited by Dale DC and Federman DD, published by WebMD Corporation, New York, 2004. URL of product www.acpmedicine.com.

engagement of the TCR, T-cell activation does not occur, tolerance develops.

Tumor antigens have an inherent disadvantage in their ability to induce an immune response, as they are often 'self-antigens' to which tolerance frequently exists. Many tumor antigens have demonstrated the ability to induce an immune response but generally they do so only inefficiently. The goal of therapeutic immunological approaches is to augment this response and overcome immunological tolerance and ignorance.

An essential quality of the adaptive immune system is the ability to distinguish self from nonself. This is achieved via the induction of tolerance to self. This process occurs primarily in the thymus and results in a state of immunological unresponsiveness. It results primarily from the interplay of an APC presenting self-antigen to T lymphocytes in the context of self-Major Histocompatibility Complex (MHC) molecules. Tolerance can also develop at peripheral sites such as the lymph nodes and spleen.

The MHC is the key to understanding tolerance. It is composed of the Human Leukocyte Antigen (HLA) system and consists of greater than 200 genes residing on chromosome 6 (see Fig. 2). Among these, the genes involved with immunity are divided into two classes, HLA class I and class II. The class I genes important for the immune response are the HLA-A, -B and -C genes. They encode for the α chain of their corresponding HLA molecule. The β chain is identical for all class I molecules and is $\beta 2$ microglobulin, encoded from a gene on chromosome 15. Both chains of all class II molecules are encoded by genes on chromosome 6. The class II HLA molecules belong to the D class and include 5 different families (M, O, P, Q, or R). Genes on chromosome 6 also encode for HLA

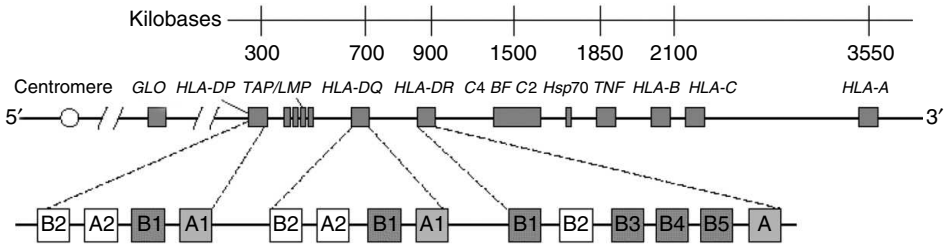

Fig. 2 Organization of *HLA* genes on human chromosome 6. The best-characterized loci of the human major histocompatibility complex (MHC), located in the *HLA* region of the short arm of chromosome 6, are depicted. Distances are shown in recombination units (centimorgans), as determined by crossover frequencies in family studies, and in kilobases, as determined by sequence analysis of fragments produced by DNases having defined cleavage sites. MHC class II molecules are encoded in the *HLA-DP*, *HLA-DQ*, and *HLA-DR* genes, and MHC class I molecules are encoded by *HLA-B*, *HLA-C*, and *HLA-A* genes. A cluster of closely linked complement genes-*C4*, *BF*, and *C2*-lies in the center of the region. There are two structural genes for *C4*, interspersed with two genes for the adrenal enzyme 21-hydroxylase. Next is the heat shock protein gene, *Hsp70*, followed by the tumor necrosis factor (TNF) genes, *A* and *B*. The orientation of the complement cluster and the *TNF* cluster has not been established, but an expanded view of this area could be depicted as-(*C4–210HA-C4B-210HB-BF-C2*)-(*HSP70*)-(*TNFA-TNFB*)-. *GLO* is a marker gene for the enzyme glyoxylase. An expansion of the class II region is in the lower portion of the figure. Each class II molecule is a heterodimer of an a and a ß chain, which are encoded in the *A* and *B* genes, respectively. Pseudogenes, which are not expressed on the cell surface, are shown in white boxes. *HLA-DP* and *HLA-DQ* have one expressed heterodimer, A1B1; *HLA-DR* has only one A chain but nine genes for B chains (four are shown in the figure). The principal expressed heterodimers for *HLA-DR* are AB1, AB3, AB4, and AB5. In the region between *HLA-DP* and *HLA-DQ* lie the closely linked *TAP1*, *TAP2*, *LMP2*, and *LMP7* genes. The *TAP* genes encode peptide transporters, whereas the *LMPf* genes encode proteasomes that fragment proteins into peptides. This cytoplasmic system is believed to be responsible for production and delivery of peptides to MHC class I molecules before their movement to the cell surface.

class III molecules. Both class I and II HLA molecules function as antigen-presentation molecules. They have a three-dimensional structure forming a groove on their surface in which a peptide can bind. It is this peptide–HLA complex that is recognizable to the TCR.

Peptide presentation in the context of HLA molecules allows the essential differentiation of self from nonself. HLA class I molecules generally present endogenous peptides derived from normal cellular housekeeping and turnover. They are present on most nucleated cells and are the predominant mechanism of TAA presentation. Class II molecules present peptides derived from exogenous sources. Their distribution is more limited, being present on phagocytic cells including dendritic cells and macrophages, B cells, activated T cells, and thymic epithelial cells.

Tolerance develops as a consequence of the deletion of self-reacting lymphocytes during maturation in the thymus. As TCR gene rearrangement is random and results in a vast repertoire, it is essential that those T cells whose receptors recognize self-antigen be inactivated. This process continues throughout life. Lymphocytes originate in the bone marrow. After migration to the thymus, Tlymphocytes whose receptors recognize self-MHC molecules are positively selected. If cells are not positively selected, as is the case for the majority of T cells, they undergo apoptosis. If a TCR recognizes self-HLA class II molecules presenting self-peptide, they also undergo apoptosis. This process is called negative selection. Tolerance developing via this mechanism requires antigens to be presented in the thymus. Many antigens however, including most tumor antigens, are not expressed in the thymus. Self-reactive T cells have been shown to exist but usually will not be immunologically reactive. These cells are not tolerant but are anergic, demonstrating immunologic ignorance. Anergy may be determined by the lack of a sufficient antigen dose, lack of adequate costimulation or by physical separation across tissue or anatomical barriers.

Antigen presented in the context of HLA class I is presented primarily to $CD8^+$ lymphocytes that are often directly cytotoxic. Antigen bound to HLA class II is preferentially presented to $CD4^+$ lymphocytes that generally are helper T cells. Following activation, secretion of cytokines results in the recruitment of additional immunological effector cells. The cellular distribution of HLA class II molecules is more limited, being primarily expressed on cells that function as professional APCs and also B lymphocytes.

3 Immune Response to Tumor-associated Antigens

As discussed above, immune effector cells capable of mediating cancer cell death fall into two broad categories. There are cells of the adaptive immune system, capable of responding in an antigen-specific manner, such as T and B lymphocytes. In addition, there are the cells of the innate immune system that recognize tumor cells in an antigen-nonspecific manner, such as natural killer (NK) cells, macrophages, and monocytes. Unfortunately, it appears that these responses are usually thwarted by a variety of means relating to properties of tumor cells that allow them to evade detection by the immune system. The immune response to tumors will be discussed below.

3.1 Adaptive Immunity

In order for a tumor antigen to incite an immune response, a carefully orchestrated and regulated sequence of events is required. Following antigen presentation, its recognition by a TCR is required. Subsequently, T-cell activation is necessary for subsequent effector function. If recognition between the TCR and the HLA–peptide complex alone occurs, without the involvement of additional costimulatory signals, the T cell will not be activated and a state of tolerance will develop. The TCR binding to the HLA–peptide complex is a relatively weak interaction and additional cell-to-cell interactions need to occur, strengthening the bond. Various adhesion molecules including LFA-1, CD2 and CD5 expressed on the T cells can bind to corresponding ligands expressed on the APC. Some of these adhesion molecules

may also be involved in cell signaling (see Fig. 1). A critical signal for T-cell activation is provided by the B7 family of ligands (CD80 and CD86) expressed on the surface of APC interacting with CD28 on the surface of T lymphocytes. Similarly, CD154 (CD40 ligand) interacts with CD40 on the surface of APCs. Additional molecular interactions between the lymphocyte and the APC also occur. Some of these are stimulatory and others are inhibitory. CTLA-4 is a structural homolog of CD28, also expressed on T cells, and its ligation by B7 expressed on APC's results in lymphocyte downregulation. Specialized APCs such as dendritic cells tend to express high concentrations of the costimulatory molecules, enhancing their ability to initiate an efficient immune response. As a consequence of these additional cell-to-cell interactions, the T cell becomes activated. IL-2 production is upregulated, resulting in further T-cell recruitment and cell survival necessary for an effective immune response.

The HLA class II molecules that present exogenous protein are synthesized in the endoplasmic reticulum. From there, they travel to the cytoplasm in vesicles that fuse with endosomes carrying exogenous peptides. The peptides are loaded into the peptide groove and the complex is transported to the cell surface for presentation to $CD4^+$ T cells (T helper cells). As most tumor antigens are self-antigens, they are primarily presented via the MHC class I pathway to $CD8^+$ cytotoxic lymphocytes. Endogenous proteins are processed by housekeeping structures called proteasomes. The resulting antigenic peptides are delivered to the endoplasmic reticulum by specialized molecules called *transporters associated with antigen processing* or *TAP* proteins. Within the endoplasmic reticulum, the class I HLA molecules bind the appropriate peptide before translocating to the cell surface for presentation to $CD8^+$ lymphocytes.

Upon recognition of antigen, cytotoxic $CD8^+$ T cells are stimulated to respond by releasing the contents of cytoplasmic granules (granzymes, perforins) that enter the target (cancer) through endocytosis and induce apoptosis.

$CD4^+$ cells respond to antigen-presenting cells with the release of a variety of cytokines. The pattern of cytokine release can be classified into a TH1 or TH2 pattern, which broadly can be defined as promoting cellular versus humoral responses, respectively. TH1 cytokines are interferon gamma (INFγ), IL-2 and tumor necrosis factor (TNF) beta while TH2 cytokines are IL-4, IL-5, IL-6, IL-10, and IL-13.

3.1.1 Control of T-cell Proliferation

After a T lymphocyte has been stimulated to proliferate, it is necessary to eventually limit the clonal expansion of these cells, lest they overwhelm the host. Described as cytotoxic, T-lymphocyte antigen-4, CTLA-4 is an important regulatory molecule expressed only on activated T cells. Nascent CTLA-4 is only expressed after T-cell activation, peaking at 2 to 3 days after the initiating event. CTLA-4, also known as CD152, has a higher affinity for CD80 and CD86 than the CD28 ligand on T cells responsible for ''signal 2'' (a costimulatory signal). The cytoplasmic domain of CD152 has an inhibitory domain, termed an *ITIM* (*inhibitory tyrosine immunoglobulin domain*), which contributes to an inhibitory signal for T-cell growth. Binding of CD80/86 to CD152 thus attenuates the immune response. The important role of CTLA-4 in moderating T-cell growth is apparent from the observation that CTLA-4 knockout mice experience lethal T-cell proliferation.

Other mechanisms of immunologic control include active suppression by certain regulatory T cells expressing CD4 and CD25, the alpha chain of the IL-2 receptor (CD25). Formerly called ''suppressor'' cells, this subset of $CD4^+/CD25^+$ T cells is emerging as a potent regulatory component of the immune system that is involved in immune tolerance. Since tumors that have already developed have evaded immunologic recognition, tolerance has apparently developed. Targeting $CD25^+$ cells in tumor-bearing animals has had therapeutic effects accompanied by immune responses to TAA.

3.1.2 Innate Immunity

3.1.2.1 **NK Cells** This remarkable cell is capable of killing cancer, virus-infected, and allogeneic cells through granule exocytosis, perforin, and granzymes. How NK cells recognize their targets, without recognizing normal cells, has been partially elucidated. NK cells express a family of inhibitory receptors: KIR (killer inhibitory receptors) that bind class I HLA. Thus, on autologous cells, NK cells are inhibited from mediating cytolysis of class I expressing cells. However, if HLA is downregulated, as it often is on cancer cells, the absence of HLA is the recognition element for the NK cell. The activity of NK cells is also mediated by their ability to release cytokines such as IFNγ and other TH1 cytokines. A subset of cells termed NKT cells exists, expressing both NK cell markers as well as TCR with limited Vβ usage, showing specificity for lipid or glycolipid antigens presented by CD1.

3.1.2.2 **LAK Cells** Lymphokine-activated killer (LAK) cells can be generated from T lymphocytes and NK cells. Using high concentrations of IL-2 in *ex vivo* cultures, large numbers of LAK cells can be generated with broad specificity against autologous and allogeneic target cells.

3.1.2.3 **Monocytes/Macrophages** Part of the innate immune system, macrophages and their precursors (monocytes) are able to directly engulf or phagocytose cancer cells. In addition, they secrete cytokines such as TNF and IFNγ, which also can kill cancer cells. Macrophages are also potent antigen-presenting cells, expressing class II HLA, that further promote immunity to cancer cells by this mechanism.

Monocyte/macrophages also link the cellular and humoral arms of the immune system through the cell surface expression of receptors for the Fc portion of immunoglobulin. Antibodies binding to soluble antigens, such as a TAA, thus target the antigen to mononuclear phagocytes by binding to Fc receptors, which leads to internalization of the antigen–antibody complex and subsequent antigen processing for display on class II HLA molecules. In turn, $CD4^+$ T lymphocytes then recognize the antigen(s) expressed by these professional antigen-presenting cells.

3.1.2.4 **Tumor Escape Mechanisms from Immune Control** In many cancers, such as malignant melanoma, there is an infiltration of immune effector cells frequently. The infiltrate generally contains both $CD4^+$ and $CD8^+$ cells, which can be shown to proliferate in response to TAA. In addition, following vaccination with TAA, an immune response frequently develops. Using tetramer analysis (the use of four linked MHC molecules with matching peptide to enhance binding to specific T cells and increase the ability to identify an antigen-specific T-cell population via flow

cytometry), tumor antigen–specific T cells have also been identified in the circulation of patients with cancer. However, even with tumor infiltrating lymphocytes or circulating tumor-specific T cells, tumors frequently progress and metastasize or do not respond to vaccination, suggesting that the effector cells are functionally impaired, or that the tumor antigen is too weak (i.e. there is tolerance). Any impairment of the immune systems' ability to eliminate tumor can affect both the innate and adaptive arms. Given the complexity involved in the initiation of an immune response, it is hardly surprising that there are many possible mechanisms that tumors can use to evade an immune response. Understanding these mechanisms and determining ways to overcome them will be essential to the development of effective immunologic therapeutic approaches. This is the subject of the following paragraphs.

Most malignancies express HLA class I molecules but not class II molecules. This mirrors the situation on normal cells. Tumor cells, including those from melanoma, breast, bladder, cervix, colon, head and neck, kidney, and lung cancers have been demonstrated to downregulate expression of class I molecules, resulting in deficient antigen presentation to $CD8^+$ T cells. One beneficial consequence of this may actually be enhanced NK-cell directed activity. NK cells have the ability to destroy infected or malignant cells. They recognize their target either via Fc receptor binding or via a pair of receptors called the ''killer activating receptor'' and the ''killer inhibitory receptor'' (KIR). The killer inhibitory receptor recognizes the MHC class I molecule and in its absence, the killer activating receptor is dominant, resulting in perforin and granzyme mediated cell lysis. However, as the malignancy generally persists following downregulation of the MHC class I molecule, the importance of this phenomenon remains unclear.

There are a number of mechanisms by which HLA loss occurs. There can be complete HLA loss, HLA haplotype loss, HLA locus loss, or HLA allele loss. Examples of $\beta 2$ microglobulin loss, deficiency of TAP-1 or TAP-2, or structural defects in MHC genes have all been reported, resulting in complete HLA loss and the inability to present antigen for recognition by $CD8^+$ T cells.

Proteasome subunit alterations have also been reported in a number of cancers. The ζ chain is an important TCR-associated signal transduction molecule essential for signaling following TCR ligation. Reduced expression of this molecule has been reported in a number of malignancies including malignant melanoma, colon cancer, and renal cell cancer. Loss of the ζ chain has been associated with a poorer survival in oral squamous cell cancers.

NFκB is a transcription factor involved in the expression of a number of molecules involved in mediating an effective immune response. Impaired NFκB activation has also been implicated in the defective T-cell responses in some malignancies including renal cell cancer (RCC). In RCC, this suppression appeared to be induced by gangliosides derived from malignant cells.

Expression of nonclassical HLA molecules, including HLA-G and HLA-E may also be important mechanisms of immune escape utilized by malignant cells. HLA-G has been reported to inhibit NK-mediated cytotoxicity and also the function of antigen-specific CTL. Similarly, expression of HLA-E has been demonstrated to inhibit the function of immune effector cells. Although classical HLA class I downregulation decreases antigen presentation to CTL, it enhances

recognition by NK cells. The expression of these nonclassical HLA class I molecules appears to interfere with this effect.

Although conflicting data has been reported, tumor-induced apoptosis of T cells may be an important mechanism of immune escape. This phenomenon has been termed *tumor counterattack*. It results from the interaction of CD95L on tumor cells with CD95 on immune effector cells, resulting in effector cell apoptosis. Another death ligand, TRAIL, and chemokines have also been implicated in tumor-induced apoptosis, resulting in immune escape.

An additional tumor escape mechanism may be secretion of immunosuppressive factors by malignant cells or from normal supportive cell populations. TGF-β and vascular endothelial growth factor (VEGF) are well-characterized examples. TGF-β is a microenvironment growth inhibitory regulatory cytokine. It may be involved in the prevention of neoplasia via its growth inhibitory properties, but, in many established cancers, resistance to the inhibitory effects has been reported. Many cancers produce TGF-β, which then inhibits the immune response, allowing enhanced tumor growth and metastasis. VEGF, in addition to enhancing tumor angiogenesis, has also been demonstrated to inhibit dendritic cell maturation and, thus, antigen presentation.

These abnormalities may occur initially in the microenvironment of the tumor cells but lymphocytes bearing similar abnormalities may also be found in the peripheral circulation. Generally, the abnormalities have been most marked in the tumor infiltrating lymphocytes, suggesting that the effects are initiated in the local tumor microenvironment. Their frequent inability to prevent metastasis suggests that the tumor inhibitory effect is dominant.

4
Immunotherapy

4.1
Passive Immunotherapy

Immunotherapy can be described as active or passive. Active immunotherapy refers to specific maneuvers taken to induce endogenous immune reactivity directed against TAA. Passive immunotherapy refers to the therapeutic administration of *ex vivo* generated intact antibodies, antibody fragments, or lymphocytes that are directed at TAA.

As a result of the expression of well-defined antigens on the surface of lymphoma and leukemia cells, a number have been identified as suitable targets for antibody-directed therapies. Ideally, these antigens will not be expressed on hematopoietic stem cells or on non-hematopoietic cells in order to minimize toxicity.

Recently, a number of monoclonal antibodies (mAb) have been approved for use in the United States of America. The first mAb to receive United States Food and Drug Administration (FDA) approval was Rituximab (Rituxan, Biogen IDEC Pharmaceuticals, San Diego, CA; Genentech, Inc, South San Francisco, CA). Rituximab is a chimeric antibody directed at the CD20 protein expressed on the surface of mature B cells. It is generated by cloning the light and heavy variable chain of 2B8, a murine monoclonal antibody, into a cDNA expression vector containing the human IgG1 heavy chain and kappa light-chain constant regions. As it contains a human antibody *backbone*, it has the ability to bind complement and also lyse target cells via antibody-dependant cellular cytotoxicity. It has also been shown to activate apoptotic pathways

and appears to enhance chemotherapy sensitivity. Rituximab is approved for use in indolent NHL but also has activity in aggressive lymphoma, especially when combined with chemotherapy.

Alemtuzumab (Campath-1H) (Wellcome, Beckenham, UK and Ilex Oncology, San Antonio, TX) is a mAb directed against CD52, a cell surface protein present on most normal and malignant B and T cells, monocytes, and macrophages. As with CD20, it is not expressed on hematopoietic stem cells. Its mechanism of action appears to be via antibody-dependant cellular cytotoxicity and complement fixation.

Epratuzumab (Amgen, Thousand Oaks, CA) is an anti-CD22 monoclonal antibody that has also demonstrated activity in NHL and continues to undergo clinical evaluation. The CD22 protein is expressed on 75% of B lymphocytes.

Two radioimmunoconjugates are currently licensed in the United States. The first is Ibritumomab Tiuxetan (Zevalin, Biogen IDEC Pharmaceuticals, San Diego, CA). This molecule is composed of the β emitter ^{90}Y linked by the chelator tiuxetan to the murine IgG1 kappa monoclonal antibody ibritumomab (IDEC-2B8). The second radioimmunoconjugate is Tositumomab (Bexxar, Corixa Pharmaceuticals, South San Francisco, CA). The radiation molecule in this case is ^{131}I, which is both a β- and γ-emitter. Both radioimmunoconjugates are FDA-approved for use in certain indolent lymphoma patients. They both target the CD20 protein on the surface of normal and malignant lymphocytes. The response rates appear to be higher than those seen following Rituximab use, most likely because of the ability of a single molecule to target greater numbers of malignant cells as a result of the path length of the β and γ emissions.

Another mAb approved for therapy is trastuzumab (Herceptin, Genentech, South San Francisco, CA). This mAb is directed to the HER-2 molecule, a member of the erbB epidermal growth factor receptor tyrosine kinase family. This receptor is overexpressed, mostly as a result of gene amplification, in 20 to 30% of breast cancers and is associated with a poor prognosis. Trastuzumab is a chimeric antibody composed of 95% human and 5% murine components. As with Rituximab, this results in a markedly reduced ability to form human antimouse antibodies and allows increased efficacy through the use of human effector mechanisms including antibody-dependant cellular cytotoxicity and complement fixation. Trastuzumab has activity both as a single agent and when combined with chemotherapy for HER2 overexpressing cancers. It is of note that patients who have received an anthracycline, either previously or concurrently, have an increased incidence of cardiotoxicity. The mechanism is unclear but does not appear to relate to HER2 expression in cardiac myocytes.

Gemtuzumab ozogamicin (Mylotarg, Wyeth-Ayerst Laboratories, Philadelphia, PA) is a humanized anti-CD33 monoclonal antibody conjugated to calicheamicin. CD33 is expressed in 85 to 90% of acute myelogenous leukemia cells. Calicheamicin is a potent antitumor antibiotic that induces double-stranded breaks in DNA. The conjugate has shown efficacy in patients with relapsed CD33$^+$ acute myelogenous leukemia. Unlike the previously discussed antibody therapies, this conjugate is rapidly internalized, following which the calicheamicin is released via hydrolysis.

Another approach to immunotherapy has involved the generation of bispecific antibodies. These are hybrid antibodies

constructed from two parent monoclonal antibodies. One antibody is specific for the tumor cell whereas the other is specific for an immune effector cells. Thus, bispecific antibodies can direct the cytotoxic activities of T cells, NK cells, monocytes, and monocyte-derived macrophages.

4.2 Active Immunotherapy

Active immunotherapy indicates that a treatment is intended to induce a specific antitumor immune response. This term generally implies the use of vaccination to treat cancer or prevent its recurrence, differing from the normal use of this term, which refers to the primary prevention of a disease, usually of an infectious nature. Although a number of vaccine approaches have been evaluated or are in clinical trials for various malignancies, no therapy evaluated thus far has been approved for routine clinical use.

The development of cancer vaccines has evolved directly from the identification of specific TAA. In addition to the use of specific known antigens, modified whole-cell preparations can function as vaccines. Whole tumor cells may be irradiated and transduced with immunostimulatory molecules such as granulocyte/monocyte colony-stimulating factor (GM-CSF). Such an approach has the potential to induce a response to a wide array of tumor antigens, but the possibility of an autoimmune response also is increased. An advantage is that the structure or identity of specific antigens does not need to be known.

For a specific antigen to be useful as a vaccine, it should be both tumor specific and immunogenic. Unfortunately, most candidate tumor vaccines are only weakly immunogenic and require modification in order to induce an immune response. The most widely applied cancer vaccine approach has utilized the immunoglobulin idiotype (the hypervariable heavy- and light-chain regions that result from a unique set of recombination events that occur during B-cell ontogeny). Every mature B cell expresses surface immunoglobulin and the idiotype of a particular B cell and all its progeny is identical and unique. In B-cell lymphomas, where at least initially all the cells are derived from the same clone, the idiotype is an ideal vaccination target. A potential drawback is that as lymphoma progresses, a specific antigen may be lost or mutate, in which case the vaccine would no longer be effective.

Animal studies have demonstrated the ability of idiotype vaccines to provide protection from tumor challenges and also to induce responses in established tumors. In indolent lymphoma patients, this approach has also induced molecular remissions in patients with minimal residual disease following chemotherapy. At present, clinical trials, currently in phase 3, are being conducted. The most common approach has been to generate idiotype protein and conjugate it to a hapten such as keyhole limpet hemocyanin, KLH). In addition, an immunostimulatory molecule such as GM-CSF is usually administered in the proximity of the vaccine to augment immunity. The schema of one trial is illustrated in Fig. 3. In this clinical trial, a lymph node representative of the patient's lymphoma is surgically excised. From this tissue, a recombinant idiotypic protein is generated, coupled to KLH, and administered subcutaneously along with GM-CSF as a vaccine. Such an approach can be taken in patients following chemotherapy when they have achieved a remission, with the goal of inducing an immune response to the idiotypic protein, thus facilitating immunologic control of

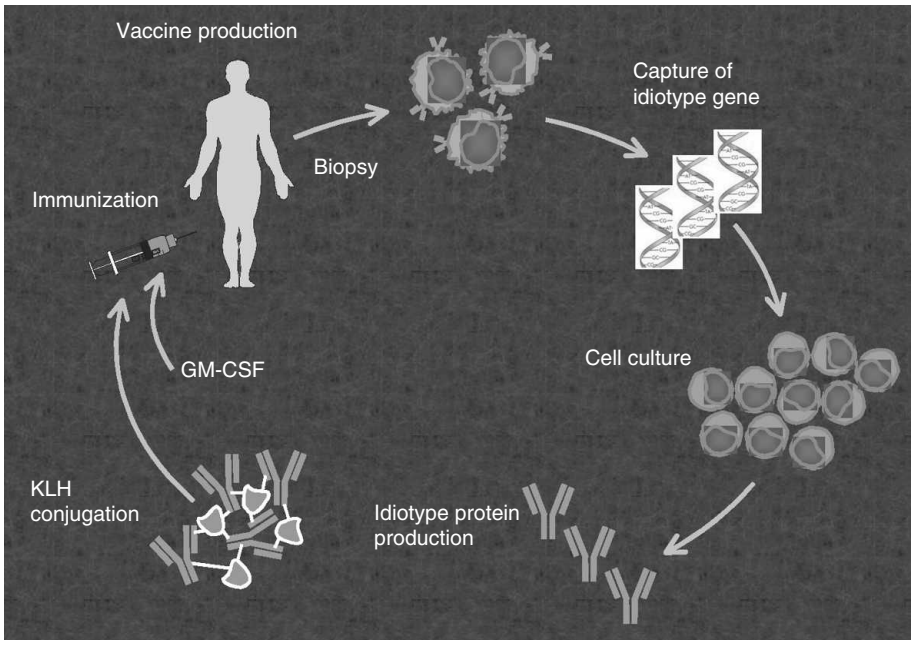

Fig. 3 Anti-idiotype vaccine preparation and administration.

any residual lymphoma cells that might lead to relapse eventually.

Another variation on this approach is the use of dendritic cells obtained from peripheral blood mononuclear cells by leukapheresis, which are cultured and then pulsed *ex vivo* with idiotype protein with or without the addition of KLH. The resulting mature dendritic cells are then returned to the patient as a cellular vaccine. Combinations of these approaches have also been utilized.

DNA vaccines are also undergoing evaluation in clinical trials and have shown efficacy in terms of the generation of specific immune responses. DNA vaccines are relatively simple to prepare. For the preparation of a DNA idiotype vaccine, variable heavy- and light-chain cDNA is isolated from tumor samples and cloned into a plasmid. In order to enhance immunogenicity, an unrelated immunostimulatory gene sequence such as that for tetanus toxoid can also be incorporated. The plasmid is bacterial derived and incorporates eukaryotic or viral promotor/enhancer transcription elements that allow efficient transcription of the target gene within the host cell. The plasmid can be delivered directly to host cells where intracellular antigen production is initiated. The main appeal of this approach, apart from simplicity, is intracellular antigen production that allows antigen presentation on the cell surface in association with HLA class I molecules, resulting in the stimulation of a cytotoxic $CD8^+$ T-cell response. In addition, secreted antigen is processed and presented by APC, resulting in both T helper response and antibody responses. In contrast, following the administration of a protein vaccine, antigen presentation is largely via professional APC, resulting predominantly in a T helper response.

Given the importance of the CTL response, if proven effective, DNA vaccination may hold certain advantages. Plasmid DNA preparation is the simplest of approaches to vaccine preparation and is in early clinical development.

The effect of tumor vaccines thus far has been difficult to evaluate. The ultimate evaluation will depend on documenting improvements in clinically relevant outcomes such as time-to-relapse or overall survival. In a disease such as indolent lymphoma, such studies would require very large number of patients followed for very long time periods, making conduct of such studies very cumbersome. Therefore, to date, surrogate immunological outcomes have been used, namely, the development of cellular or humoral immune responses. However, there remains significant controversy regarding the relative importance of each of these components of the immune system in mediating responses to tumor vaccination. Further, as discussed earlier, the development of a response may not correlate with therapeutic benefit because of local immune suppressive factors produced locally by tumors. Large-scale clinical trials with clinical outcomes will ultimately be required to demonstrate the benefits of this approach and the particular clinical situations where maximal benefit can be achieved.

4.3 *Ex vivo* Generation of CTL

Efforts by countless scientists in academia and industry are continuing to harness the cells and other components of the immune system to fight cancer. The generation of cytotoxic T-cell lines or polyclonal populations of cytotoxic T cells has been a major component of this multiplicative approach. CTLs can be grown from primary tumors in the case of melanoma and other solid tumors. In addition, they can be grown from the peripheral blood of patients with hematologic malignancy. Using cytokines such as IL-2, IL-12, IL-13 and monoclonal antibodies stimulating the costimulatory receptors CD28 and CD3 allows the generation of large numbers of CTL, which can then be cloned by limiting dilution. Efforts to achieve clinical responses in patients with solid tumors have been relatively unsuccessful to date. However, armed with increased knowledge of tumor antigens, a multitude of cytokines, and greater insight into the requirements for cellular activation, substantial progress is finally being made. Recently, it was shown that complete responses could be achieved in melanoma patients given CTLs after a brief treatment with cytotoxic chemotherapy to allow ''space'' for the incoming lymphocytes to proliferate and mediate cytotoxicity. This clinical trial illustrated the principle that attacking cancer requires a combination of various treatment modalities. Investigators are currently working on expanding T cells to treat leukemia, lymphoma, and a multitude of solid tumors. Other approaches under study include the blockade of CTLA-4 on T cells reacting to TAA. Such blockade allows more robust growth of T cells by neutralizing the negative regulatory activity of the CTLA-4 molecule.

4.4 *Ex vivo* Generation of Dendritic Cells (DC)

Dendritic cells are very potent antigen-presenting cells. They can be generated *ex vivo* from peripheral blood monocytes or bone marrow hematopoietic progenitor cells. Dendritic cells can also be derived

directly from myeloid leukemia cells by G- and GM-CSF and IL-4. Once generated, dendritic cells can be pulsed with tumor peptide epitopes for display on surface HLA. In addition, dendritic cells may be loaded with tumor cell lysates or apoptotic bodies, allowing display of uncharacterized tumor antigens from heterogeneous cell populations. Dendritic cells(DC) may be infused *in vivo* or may be injected intratumorally to present antigens to local T cells for antitumor effects. Promising clinical trials have been reported at the time of this writing and there is considerable hope that this form of treatment will be useful for patients with cancer.

4.5 *Ex vivo* Generation of NK Cells

Generation of large numbers of NK cells can be achieved through *ex vivo* expansion using IL-2. However, clinical therapeutic results have been somewhat disappointing to date. This probably is due to the inability of infused natural killer cells to track *in vivo* to sites of tumor. Further insights into the mechanisms and controls of cell trafficking will hopefully improve the results of NK-cell mediated therapy.

4.6 Summary and Conclusions

Prevention and effective treatment of human malignant disease by the immune system is the goal of modern immunological and clinical research. Efforts thus far have suffered in the clinic from a lack of basic understanding of the molecular biology and physiology of tumors and the immune system. Recent advances in the understanding of the biochemical nature of tumor-associated antigens, the mechanism of antigen presentation to the immune system, and the means by which tumor cells evade immune elimination have given rise to a number of more rational and targeted approaches to immunotherapy. In addition, the advent of powerful engineered molecules including monoclonal antibodies, cytokines, and chemokines and the ability to manipulate, purify, and expand cells of the immune system *in vitro* have provided the tools to test many new therapeutic approaches to the treatment of human malignancy.

Keywords

Cytokines
Low molecular weight, soluble proteins that mediate signaling and affect cellular behavior by specific binding to receptors on cell surfaces. Cytokines are pleiotropic, redundant, and multifunctional.

Chemokines
A class of cytokines with chemoattractant properties, which enables migration of leukocytes to sites of inflammation.

Inflammation
Recruitment of body defenses against an invading organism or tissue damage and ensuing repair of damage.

Leukocytes
White blood cells including the lymphocytes and most myeloid cells, which perform various significant immune functions.

Phagocytosis
The process of engulfment of invading particles within an invagination of the phagocyte cell membrane.

Prior to the late-1960s, most studies on vertebrate immune systems focused on the recognition and killing mechanisms of adaptive immunity. The evolutionarily ancient mechanisms of innate immunity, generally thought to be nonspecific and obsolete, were, for the most part, overlooked. However, the relevance of innate systems has become apparent in recent decades, especially with the discovery of Toll-like receptors and with the ability of pattern-recognition receptors to stimulate effective immune responses via the induction of genes and cytokine expression. This review focuses on the complex interplay at the molecular level, between innate immune activation and adaptive immune responses and on how this relationship is essential for host defense.

Current molecular studies of innate immunity seek to clarify the interconnectivity between innate and adaptive phenomena and to understand the mechanisms of innate defense in their own right. These include examinations of the ligand specificities and structural interactions of the innate immune receptors, gene expression regulation during the maturation of immune responses, and the interplay of signal transduction pathways that culminate in induced innate responses to various pathogens. The perception of the innate immune system as a highly

evolved biological design rather than a relic from ancestral species is allowing significant advances to be made in modern immunology.

1
Essential Components and Functions of the Immune System

1.1
Innate and Adaptive Immunity

The principal responsibilities of an immune system are to recognize a wide variety of pathogens and to destroy those pathogens while tolerating the tissues of the host organism. Innate immunity is the most universal and expeditious type of immunity, having evolved over the last hundred million years or so to accomplish these tasks. It includes physical barriers, such as the skin and epithelia that protect our internal organs, and the cells that bear innate immune receptors, such as macrophages, dendritic cells (DCs), neutrophils, basophils, eosinophils, mast cells, and natural killer (NK) cells. These white blood cells derive from myeloid and lymphoid precursors in the bone marrow. An encounter with a pathogen leads to the prompt removal of the agent or recruitment, activation, and differentiation of short-lived effector cells, which have further capacity to rid the host of most infections. Innate immune mechanisms work effectively against a broad range of pathogens during the first encounter with a pathogen. The response does not require an extended period of time to develop, due to the fact that the complete protein receptors are encoded in the germ-line DNA. Expression of innate immune receptors thus does not seem to involve either gene rearrangement or clonal expansion.

While the majority of organisms survive utilizing only innate immune mechanisms, vertebrates have developed secondary means for pathogen detection and eradication. When innate immunity is circumvented or overwhelmed, an adaptive system is utilized. Adaptive immunity relies on activated lymphocytes to generate highly variable antigen receptors, which provide specific recognition of protein, carbohydrate, lipid, and nucleic acid moieties of pathogens and foreign material. These recombinant receptors, the immunoglobulins and T-cell receptors (TCR), are capable of recognizing virtually any pathogen. Each lymphocyte generates a unique antigen receptor by rearrangement of multiple gene segments. Activated cells undergo selection and clonal expansion for four to five days in order to produce large quantities of these antigen-specific receptors. Binding events by these molecules activate downstream humoral and cellular effectors, many of which are components of the innate defenses. The adaptive immune system is thus dependent on the same effector mechanisms as innate immunity but imparts activation and antigen specificity to the process. Adaptive immunity also bestows immunological memory to a host, providing enhanced protection against reinfection by the same pathogen.

Host defense by innate immune mechanisms controls infection by pathogens with common molecular surface motifs and by those that induce interferons and nonspecific defenses. But innate defenses do not have the ability to recognize and fight a broad range of pathogens. Prior to infection, viruses are rarely recognizable by macrophages as the viruses do not have many invariant structures. Other pathogenic organisms can produce a capsule that conceals the otherwise

susceptible surface molecules to avoid detection. Significantly, innate defenses are also unable to elicit long-lasting memory of specific pathogens. This ability is limited to the adaptive immune processes found exclusively in vertebrates. Nevertheless, the large number of invertebrate species that exist on earth (much greater than vertebrates) attests to the success of the innate immune system.

The beneficial features unique to the adaptive immune responses include, great diversity for antigen recognition, specificity for a particular antigen or pathogen, and the ability to confer immunological memory after an encounter. However, adaptive immune responses do not become activated until approximately three days postinfection and the production of their primary components is delayed by five days. During this delay, the innate immune system limits the proliferation and spread of pathogens until the mechanisms of adaptive immunity achieve maximum potential. In the absence of innate immunity, acquired immune responses are inadequate for host protection. In contrast, the potency and pathogenicity of antibody-mediated effector functions can be seen in autoimmune diseases, allergic responses, and allograft rejection, which all result from the misregulation of adaptive immunity. This inopportune recognition of nonpathogenic material or self is generally confined to the adaptive immune response; autoreactivity has not been observed in organisms that accommodate only the components of innate immunity.

Immunological memory, preserved in the form of long-lived cells that persist in tissues and bone marrow, can last for months, years, or a lifetime and accounts for the efficacy of vaccines. These memory cells are readily activated by a subsequent encounter with antigen and can rapidly differentiate into effector cells. Unfortunately, this memory is confined to the individual challenged by the pathogen. Apart from passive immunization, such as transfer of antibody from mother to child, there is little carryover to future generations.

Despite the limitations of the individual systems, the benefits of incorporating two systems for immune defense are obvious. The strength of the adaptive immune response lies in its great diversity and specificity, providing complexity to the innate systems in the ability to recognize exquisite details of pathogenic organisms. Meanwhile, the innate defenses allow rapid discrimination of self from nonself and delay the need for adaptive immunity during the time required to generate effector lymphocytes. Chemokine secretion recruits leukocytes to appropriate sites, and cytokine-mediated signals provide optimal interplay between the divisions. In this manner, the innate immune system can direct the adaptive immune system in combating the infection. Thus, the synergy between the innate and adaptive mechanisms creates successful host defenses in vertebrates.

1.2 Constitutive and Inducible Defenses

The components of innate immune systems, found in most multicellular organisms, can be divided conceptually by function into the afferent and efferent limbs (Table 1). These defense mechanisms may also be discussed in terms of the point at which they are active during the course of infection (Table 2). The constitutive defense mechanisms include physical, mechanical, and chemical barriers that prevent initial invasion

Tab. 1 Afferent and efferent components of the innate immune system.

	Afferent function	***Efferent function***
Humoral components	Soluble innate immune receptors such as LPS-binding protein, CD14, collectins, properdin, complement component C3b, and C-reactive protein (pentraxin)	Secreted and cytosolic cytokines, antimicrobial peptides, enzymes, late components of complement, lactoferrin, and acute-phase proteins
Cellular components	Surface-bound receptors including toll-like receptors, MSR, MMR, and NOD proteins	Cellular enzymes, cell adhesion molecules, reactive oxygen species, and other antimicrobial substances

Tab. 2 Constitutive and inducible innate defense mechanisms.

Component	***Location***	***Function***
Physical factors		
Intact skin	External	Physical barrier to the entrance of microbes.
Mucous membranes	Internal cavities	Physical barrier to the entrance of microbes
Mucus	Respiratory and digestive tracts	Trap microbes
Epiglottis	Respiratory tract	Prevent microbes and particles from entering trachea
Hair	Nose	Filter microbes and dust
Mechanical factors		
Cilia	Upper respiratory tract	Trap and remove microbes and dust
Tears	Eyes	Dilute and remove irritating substances and microbes
Saliva	Oral cavity	Wash microbes from mucosal surfaces
Urine	Urogenital tract	Wash microbes from urethra
Chemical factors		
Gastric juice	Digestive tract	Destroy bacteria and toxins in stomach
Acid pH	External	Discourage growth of microbes
Unsaturated fatty acids	Various	Antibacterial in sebum
Other defenses		
Lysozyme	Various	Antimicrobial substance in perspiration, tears, saliva, nasal secretions, and tissue fluids.
Interferon (IFN)	Circulation	Protect host cells from viral infection
Complement	Circulation	Lyse microbes, promote phagocytosis, contribute to inflammation (leukocyte recruitment)
Phagocytosis	Peripheral tissues and circulation	Ingestion and destruction of foreign particles
Inflammation	Peripheral tissues	Confine and destroy microbes, repair tissues
Fever	General	Inhibit microbial growth, aid repair

by potential pathogens. Rigid junctions between epithelial cells effectively separate the interior milieu from the external environment. Production of a glycoprotein-rich mucus layer prevents adhesion of the microorganism to the epithelium, and movement of hairlike cilia aids in foreign-particle clearance. Antimicrobial enzymes and peptides (see Sect. 5.2) are also continuously expressed at mucosal epithelia, which have frequent exposure to microbes. The destructive capability of these substances affects microorganisms but is not directed at host cells and tissues. This distinction between self and nonself is accomplished by compartmentalization, or specific activity against microbes (e.g. susceptibility of bacterial cell walls, but not host cell membranes, to lysozyme and defensin). Yet another mechanism of defense is the colonization of epithelial surfaces with commensal microbes. These normally nonpathogenic bacteria compete with harmful microorganisms for nutrients and sites of attachment. Some bacteria even produce their own antimicrobial substances, or bacteriocins, to help outcompete other species.

If a focus of infection is established, inducible host defense mechanisms including local inflammatory responses are initiated at sites of infection. Heat, pain, redness, and swelling associated with inflammation are due to increased vascular diameter, increased endothelial adhesion, and increased vascular permeability mediated by cytokines. Pathogens that have penetrated host tissue are recognized by macrophages, which can phagocytose the offending microbes. Macrophages may also release cytokines, chemokines, and inflammatory mediators, which include tumor necrosis factor-α (TNF-α), prostaglandins, leukotrienes, and platelet activating factor. Another set of inflammatory mediators is produced via the activation of the complement cascade (discussed in Sec. 5.1), which also occurs in response to pathogen binding. These molecules can stimulate an acute-phase response, activate natural killer (NK) cells, and trigger interferon production and nonspecific defenses by regulating transcriptional activation. Cytokine production is also responsible for instructive cross talk to antigen-presenting cells and adaptive immune mechanisms.

2 Molecular Basis of Innate Immunity

2.1 Evolution

The innate immune system has its origins in the bilateria approximately one billion years ago. Today, nearly all multicellular organisms rely on derivative innate strategies for protection from infection. For example, mammals utilize skin as a barrier to pathogen invasion, whereas insects have an exoskeleton that performs the same function. Following this first tier of immune defense, specialized immune cells and tissues are induced to contain infections. White blood cells and liver of mammals function analogously to the hemocytes and fat body of certain insects in this respect. Diverse organisms have also evolved similar mechanisms for the recognition of infection and for swift responses to infection. Animals and plants alike have acquired the ability to recognize invariant patterns associated with pathogenic microbial organisms. In plants, these patterns are termed *general elicitors of plant defense*, while in animals

they are designated *pathogen-associated molecular patterns*. Amazingly, plant receptors recognize patterns similar to those reported to activate innate defense mechanisms in mammals and insects, and some of the specific receptors and signaling molecules used appear to share homology. Genomic evidence also exists for common pathways for transcriptional activation in plants, vertebrates, and invertebrates. But while *Drosophila* produce many different antimicrobial peptides to combat fungal and bacterial infection, mammalian systems produce fewer of these types of peptides and rely more on cytokine-mediated inflammatory responses. It has not been conclusively determined whether similarities between diverse animal and plant defense pathways are due to conservation through a billion years of evolution or whether the systems converged independently.

The mechanisms of adaptive immunity are thought to have developed much later on the evolutionary timeline in the context of a functioning innate immune system. The genes of the TCR and antibody first appeared in the cartilaginous fish, such as shark, approximately 400 million years ago. The origin of gene rearrangement and junctional diversity in immune receptors is thought to be an invasion by a retrotransposon. The recombinase-activating genes (RAGs), required to generate diversity in the receptors, are encoded in opposite orientations in the genome, and lack introns, similar to the bacterial transposases. Additionally, recognition signal sequences (RSSs) are present at the 3′-end of the V-gene segments and 5′-end of the J-gene segments. These properties support the notion of the integration of RAGs and RSSs into a gene for an ancient antigen receptor.

2.2 Affinity and Specificity

The innate and adaptive arms of the immune system differ in their modes of recognition. While antibodies are known for their exquisite specificity for antigens, the innate immune system recognizes a few highly conserved structures found in a large variety of microorganisms. The molecules targeted are vital components of microbes, so they are not often altered by mutation. Central to our understanding of the molecular basis of innate immune recognition are investigations of the receptor complexes that recognize these molecules. Binding of these receptors mediates ingestion of pathogens, allows cells to recognize chemotactic substances and migrate toward sites of infection, and induces effector molecules that regulate further immune responses. The affinities of innate immune receptors for their targets can run in the nanomolar range, for example, soluble CD14 binds Lipopolysaccharide (LPS) from a *Salmonella* strain with dissociation constants of 4.1×10^{-8} M and 7.1×10^{-9} M, in the absence and in the presence of LPS-binding protein (LBP) respectively. In comparison, affinity constants for antibody–ligand binding usually range from 10^{-8} M to 10^{-10} M, and TCR MHC–antigen affinities run in the range of 10^{-4} M to 10^{-5} M.

Importantly, innate receptors can distinguish nonself from self. While the receptors of T- and B lymphocytes allow great variability in adaptive immune recognition, they cannot determine the nature of the antigen. Although usually rare, adaptive immune responses to nonpathogen antigens can potentiate autoimmunity, allergy, or tissue-graft rejection.

3
Innate Immune Recognition

3.1
Pathogen-associated Molecular Patterns

Pathogen-associated molecular patterns (PAMPs) are the main targets of innate immune recognition. PAMPs are usually formed by constitutively expressed structures essential to the survival of a microbe and are often shared among members of large groups of microorganisms. Significantly, PAMPs are motifs that are not found on host cells. Host immune systems have evolved to take advantage of the following three characteristics. First, constitutive expression of the PAMP allows constant recognition regardless of pathogen life cycle, and because the structure is indispensable, it is unlikely to acquire mutations. Second, the host can employ a limited number of germ-line-encoded receptors to recognize a very broad range of microorganisms and can customize its responses to them because the target molecules are class specific. And third, the presence of a PAMP allows the host to distinguish itself from the foreign microbe. Lipopolysaccharide, peptidoglycan, and lipoteichoic acids (LTA) are examples of PAMPs that are fundamental components of bacterial cell walls and are not present on eukaryotic cells. Other PAMPs include the CpG motif present in bacterial DNA, components of flagella, and viral components. The detection of these PAMPs provides some information on the identity of the pathogen.

Lipopolysaccharide is the principal outer-membrane constituent of gram-negative bacteria. It is an amphipathic molecule consisting of a hydrophilic polysaccharide core and O-antigen and a hydrophobic glycolipid anchor termed *lipid A* (Fig. 1). The core region contains Kdo (3-deoxy-D-*manno*-octulopyranosonic acid) and heptose-sugar residues, while O-antigen is composed of a sequence of repeating units of oligosaccharide, which varies between bacterial species or strain. Lipid A is composed of a phosphorylated diglucosamine carrying acyl residues and is the primary immunostimulatory component of LPS. The primary effects of LPS were first reported over a century ago, but properties of this molecule continue to be studied today. LPS, the source of bacterial endotoxin and lipid A, is, to a degree, responsible for systemic inflammatory response syndrome (SIRS) and septic shock associated with gram-negative bacteremia. LPS stimulates the secretion of cytokines from leukocytes, namely, TNF-α, interleukin (IL)-1, and IL-6, and causes changes in body temperature, heart rate, respiratory

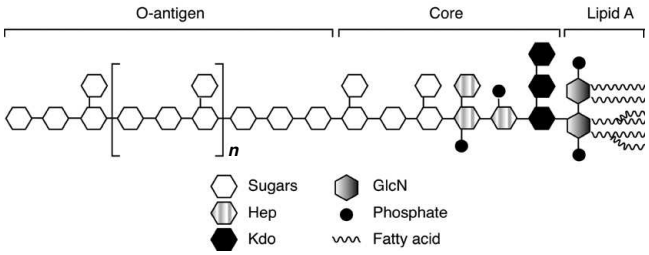

Fig. 1 General structure of LPS.
Kdo = 3-deoxy-D-manno-octulopyranosonic acid; GlcN = *N*-acetylglucosamine; Hep = heptose.

function, and leukocyte circulation. The resultant hypotension, systemic organ failure, and other significant complications lead to hundreds of thousands of deaths per year from this syndrome. However, most LPS-activated responses resolve infections quickly by initiating killing of the microbe.

Peptidoglycan and LTA may be the causative reagents in gram-positive bacterial septic shock. Peptidoglycan is a network of carbohydrate polymers covalently cross-linked by proteins, which composes the structural core of the gram-positive bacterial cell wall. Linear macromolecules are made of alternating *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNAc) residues joined by $\beta-(1-4)$ linkages. Tetrapeptide side chains attached to MurNAc form covalent bonds with adjacent polymers directly through its side chains or through peptide interbridges. Teichoic acids, also found in the cell wall of gram-positive organisms, are polymers of glycerol and ribitol, linked by phosphodiester groups. Teichoic acids are connected to either the peptidoglycan itself or to plasma membrane lipids (LTA). The biological functions of LTA are known to include binding of metal cations. The LTA structure consists of two fatty acid tails and a long charged hydrophilic chain. The classic *Staphylococcal* LTA is an unbranched 1,3-linked glycerophosphate chain bound covalently to a membrane diacylglyceroglycolipid. LTAs are structurally distinct between bacterial species, varying in fatty acid composition, chain length, glycosyl substituents, glycolipid structures, spatial distributions, and charge densities. One or more of these features may explain the variable immunological properties of LTA from different sources. The fatty acid-containing lipid anchor and additional structural components on the polyglycerophosphate backbone contribute to the immunostimulatory activity of LTA. Recent studies have suggested a key role of D-alanine substituents in inducing cytokine secretion. Although the effects of LTA alone are not particularly severe, it can act synergistically with peptidoglycan, leading to systemic inflammation and multiple systems failure via induction of TNF-α and IFNγ.

3.2 Pattern-recognition Receptors

Pattern-recognition receptors (PRRs) detect conserved structures on microorganisms during innate immune defense. PRRs are structurally and functionally heterogeneous. They may contain distinct motifs such as C-type lectin domains, scavenger receptor cysteine-rich domains, and leucine-rich repeat (LRR) domains. The receptors may be secreted, or expressed on the cell surface, within intracellular compartments or in the cytoplasm. PRRs function through opsonization, complement activation, proinflammatory signaling pathways, phagocytosis, and the induction of apoptosis.

Secreted recognition molecules include the proteins synthesized in the liver during the acute-phase response, such as mannan-binding lectin (MBL), C-reactive protein (CRP), and serum amyloid P component (SAP). MBL is a collectin (contains both collagen-like and C-type lectin domains) that binds specifically to the carbohydrate arrays accessible on many microorganisms. MBL–ligand binding may be inhibited by mannose, fucose, *N*-acetylglucosamine, and DNA, but avidity is greatest for the terminal mannose residues typically present on microbial surfaces. By comparison, on vertebrate

cells, such carbohydrate patterns are usually masked by sialic acid residues, so for the most part, MBL recognizes only pathogens. MBL can effectively neutralize bacteria by binding or can opsonize bacteria and activate complement via an associated serum protease, MASP-2, initiating the lectin pathway by cleaving complement proteins C2 and C4. CRP and SAP are pentraxins that opsonize bacterial surfaces containing phosphorylcholine (PC). Both proteins display calcium-ion-dependent binding, but SAP has a slightly lower avidity for PC than does CRP. The distribution of PC in polysaccharides of foreign molecules and damaged host membranes allows CRP and SAP to recognize pathogens and altered self. CRP is found in trace amounts in human serum, but its concentration can elevate dramatically in response to inflammation and tissue necrosis. Upregulation occurs at the transcriptional level in response to cytokines IL-1β and IL-6. Multivalent binding of CRP activates complement by initiating assembly of a C3 convertase. Additionally, the protein interacts with FcγRI receptors, mediating phagocytosis and leading to the generation of proinflammatory cytokines. The topology and chemical composition of the CRP ligand-binding site has been determined by crystallography. SAP shares many features with CRP, including remarkable structural similarity, 59% sequence homology, and the ability to activate complement. Plasma LBP mediates the binding of minute amounts of LPS to glycosylphosphatidylinositol-anchored membrane CD14, triggering a proinflammatory response in macrophages, which is crucial to control infection by gram-negative pathogens. The CD14 LPS receptor complex may also involve molecules of TLR-4 and MD-2.

Several cell surface receptors function as PRRs to facilitate direct phagocytosis of microorganisms. The macrophage mannose receptor (MMR) is a C-type lectin found on macrophages but not on monocytes or neutrophils. The protein contains eight carbohydrate-recognition domains, the fourth of which is central to ligand binding, and like MBL, it can bind mannose, fucose, and *N*-acetylglucosamine. MMR is closely related to the dendritic cell PRR, DEC205, which is also a mediator of phagocytosis. Macrophage scavenger receptors (MSRs) bind a variety of charged ligands such as double-stranded RNA (dsRNA), LPS, and LTA, coordinating responses to a variety of viral and bacterial pathogens. MSRs also participate in lipid homeostasis by endocytosing acetylated and oxidized low-density lipoprotein. PRRs for a broad range of ligands have also been identified in invertebrates. These include the broad range β2integrin CR3, peptidoglycan recognition protein (PGRP), and gram-negative binding protein (GNBP), which have counterparts in the mammalian Toll-like receptors (TLRs).

Recognition systems also exist in the cytosol to prevent replication of intracellular pathogens. Activation of dsRNA-dependent protein kinase (PKR) inhibits initiation of viral and cellular protein synthesis by phosphorylating the translation initiation factor eIF2α. Interferon-inducible 2′,5′-oligodenylate synthase (OAS) also binds viral dsRNA within cells. Resulting synthesis of ppp(A2'p)nA oligoadenylates activate the RNaseL endonuclease, which cleaves RNA. This OAS/RNaseL pathway is particularly important in the antiviral action against picornaviruses. Members of the NOD (nucleotide-binding oligomerization domain) family are proteins containing a CARD, NOD, and LRR region. After PAMP

binding, protein kinase RIP2 associates with CARD domains and activates MAP kinase and NFκB signaling pathways. NOD proteins have been shown to bind LPS, but the full extent of ligand specificity for these molecules has not been elucidated. Downstream transcriptional activation by PKR (in TLR signaling) and NOD induces IFN genes.

3.3 Toll-like Receptors

Multiple innate immune receptors are able to distinguish nonself from self, as well as recognize individual classes of pathogens. Among diverse organisms, there exist genetic and structural homologies between the protein receptors and similarities in the pathways of immune-mechanism activation. The identification of the mammalian Toll-like receptor (TLR) family, homologs of the *Drosophila* Toll (Toll-1) protein, provided the primary evidence for evolutionary conservation within eukaryotic immunity. Both Toll and the TLRs are single-transmembrane spanning receptors possessing a variable number of extracellular amino-terminal LRR motifs, followed by a cysteine-rich domain. At the carboxy-end of the Toll/TLR transmembrane domain is an intracellular signaling domain, homologous to that of the cytoplasmic interleukin-1 receptor (IL-1R). It is therefore called the Toll/IL-1R (TLR) domain (Fig. 2).

The original function identified for Toll was the development of dorsoventral polarity in the fruit-fly embryo. It has since been discovered that Toll is required to combat systemic fungal infection in *Drosophila* by inducing the expression of drosomycin, an antifungal peptide. In addition to Toll, there are at least eight related homologs (Tolls-2–9), which appear to have functions in *Drosophila* development.

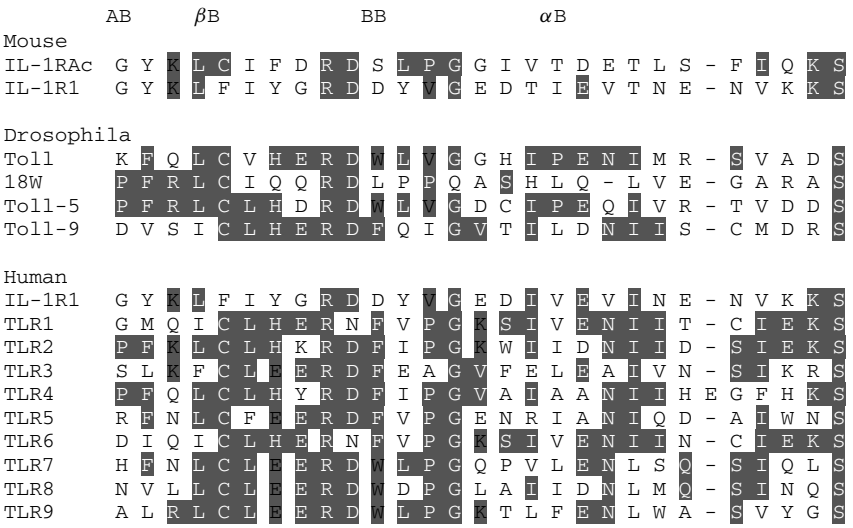

Fig. 2 Sequence alignment of the TLR domain-signaling region of mouse and human IL-1R proteins, *Drosophila* Toll proteins, and human TLRs. Residues conserved in at least four sequences are shaded. The greatest homology between *Drosophila* and human proteins occurs between the cytoplasmic domains of Toll-9 and TLRs 1, 2, 4, and 6.

Of these proteins, Toll-2 (or 18 Wheeler, 18 W) and Toll-5 have been found to have involvement in immune responses. Mutagenesis has shown that 18 W facilitates the recognition of gram-negative bacterial pathogens and the subsequent production of attacin, an anti-gram-negative bacterial peptide. Likewise, it has been suggested that Toll-5 acts as a pattern-recognition receptor mediating local antifungal responses in the absence of Toll-1/Spätzle signaling. These Toll family members respond to different pathogen classes and induce appropriate effector responses, presumably on the basis of PAMP recognition, that is, antibacterial and antifungal peptides are differentially expressed in response to the presence of bacteria or fungi. Significantly, these findings demonstrated that an organism lacking an adaptive immune system can detect infection as well as determine the type of pathogen present, entirely on the basis of innate immune mechanisms.

Mammalian TLRs may also be able to distinguish between pathogen classes. The TLRs function as PRRs in mammals, binding to microbial products to activate host defense responses. To date, 11 identified mammalian TLRs have been described, differing in sites of expression, ligand specificity, and downstream effector activation. Ten TLR genes (TLRs 1–10) are dispersed throughout the human genome, whereas mice encode nine of these, plus two additional paralogs not present in humans. Surface expression is usually low in monocytes ($\sim 10^3$ per cell) and DCs ($\sim 10^2$ per cell) but may be enhanced in response to various stimuli. TLR expression is also observed in adipocytes, myocytes, vascular endothelial cells, and intestinal epithelial cells. TLR4, the first mammalian TLR identified, when activated induces the expression of inflammatory cytokines and costimulatory molecules in macrophages. The murine TLR4 protein responds to the class of gram-negative bacteria. The molecular signature detected in this case is LPS. Although other PRRs were previously known to initiate signals in response to LPS, the existence of an additional coreceptor was hypothesized. The cellular response to LPS occurs through interaction with a circulating LBP and a GPI-linked surface receptor, CD14, followed by activation of TLR4. Point mutations in the TLR4 TIR domain led to defective LPS signal transduction, as did the absence or deletion of TLR4. These results demonstrated the necessity for a functional TLR4 in the recognition of this essential component of gram-negative bacteria. TLR4 has also been shown to mediate signals initiated by other endogenous and exogenous compounds (e.g. Taxol), respiratory syncytial virus protein F, heat shock protein 60, and domain A of fibronectin. Other conserved PAMPs have been shown to signal immune responses via other members of the TLR family, such as peptidoglycan by TLR2 and flagellin by TLR5. It seems likely that elucidation of newly discovered mammalian TLR homologs will elucidate the specificity of one or more of the homologs for mannan or glucan, and of fungal and mycobacterial pathogens for lipoarabinomannan or muramyldipeptide PAMPs, respectively.

Structural variation among TLRs is mainly due to differences in the numbers of LRRs, which affect the proteins' sequence length and molecular weight (Fig. 3). LRRs are found in a wide array of molecules, including proteoglycans, adhesion molecules, enzymes, tyrosine kinase receptors, and G-protein-coupled receptors. Toll and 18 Wheeler have 22 and 31 LRR ectodomains respectively, comparable to the 18, 19, 24, and 22 LRR-containing

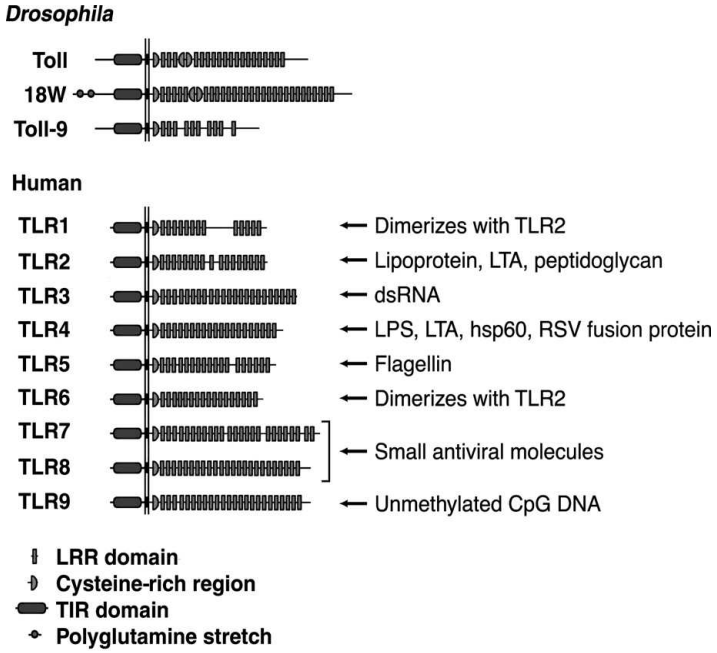

Fig. 3 Schematic representation of human TLR domains and their stimuli. Adapted from Imler, J.-L., Hoffmann, J.A. (2001) Toll receptors in innate immunity, *Trends Cell Biol.* **11**, 304–311.

TLRs 1–4. The LRRs are terminated by a domain of cysteine residues; however, the human TLR chains have lost an approximately 90-residue cysteine-rich region found variably in the *Drosophila* proteins. The extracellular domain of 18 W contains 16 putative N-glycosylation sites and a single glycosaminoglycan site. The cysteine clusters allow the receptors to form a compact module with paired termini that can be inserted between any pair of LRRs without altering the overall fold of the extracellular region. Two hydrophobic regions are apparent in the protein structure of 18 W. One corresponds to a signal peptide and the second to a transmembrane domain. The intracellular moiety of 18 W is about 380-aa long and consists of two domains, the first of which shows significant homology to the cytoplasmic domain of IL-1R. Interleukin-1 receptor, Toll, and 18 W share six conserved stretches of amino acids. The second domain consists of a glutamine-rich repeat.

Upon ligand binding, TLRs activate expression of host defense genes. Some of the intracellular signaling pathways induced are similar to those employed by IL-1R (Fig. 4). These pathways are coupled to the nuclear translocation of Rel-type transcription factors. An adaptor, such as MyD88, is first recruited to the receptor complex, mediating an interaction with the receptor via its amino-terminal TIR domain and associating with protein kinase IRAK1 through a carboxy-terminal death domain. IRAK1 undergoes autophosphorylation, which is thought to be followed by IKK-β activation via TRAF6 and by degradation of IκB. As a result, NFκB may translocate into the nucleus

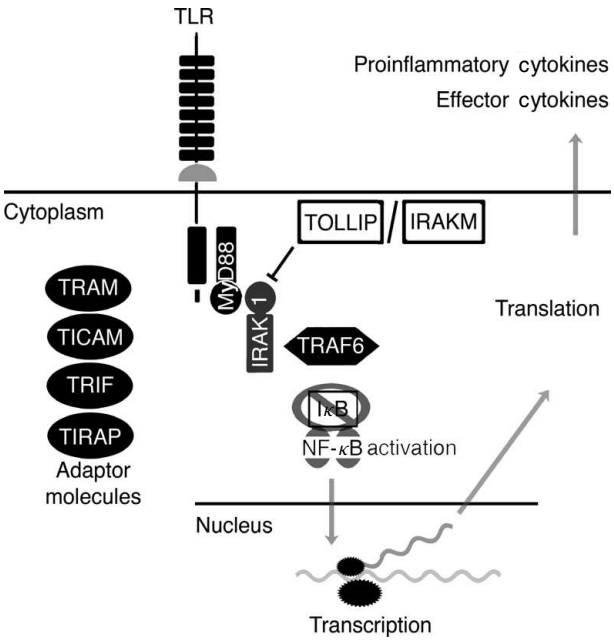

Fig. 4 MyD88-dependent and -independent TIR domain signaling. The MyD88-dependent pathway is common to all TLRs. Upon binding, TLRs induce the recruitment of MyD88 via its TIR domain, which activates IRAK1 by phosphorylation. IRAK1 then associates temporarily with TRAF6, eliciting downstream signaling, NFκB activation, and resultant production of proinflammatory cytokines such as TNF-α, IL-1, and IL-12. IRAK1 activity is negatively regulated by Tollip and IRAK-M. Some differences between signaling pathways induced by individual TLRs may be attributed to distinct adaptor protein usage. TLR4 and TLR2 MyD88-dependent signaling requires the adaptor TIRAP/Mal. IFN-β production in response to double-stranded RNA recognition by TLR3 is mediated by TRIF/TICAM-1 in a MyD88-independent manner. TRAM/TICAM2 is another adaptor pertinent to the TLR4 MyD88-independent pathway.

and allow transcription of appropriate targets. Although some TLRs are dependent on this conserved Toll signaling pathway (TLR2 and TLR9), MyD88 is not required for other TLR signaling events, such as the MyD88-independent pathway associated with the stimulation of IFN-β and the maturation of DCs. Additional regulatory mechanisms and downstream signals must also be in place to effect responses appropriate to the initiating stimulus. In particular, TLR4 activates transcription of NF-kappaB- and interferon regulatory factor (IRF)-3/IFN-inducible genes in macrophages and dendritic cells in a MyD88-independent manner, potentially by another TIR domain-containing adaptor protein, TIRAP. Data has suggested that TLRs 1, 2, and 6 can also use this alternative adaptor molecule. A third TIR-containing adaptor molecule (TICAM-1), which binds TLR3, inducing interferon-β

has also been described. Suppression of signaling may also occur by association of either of the proteins Tollip or IRAK-M with TRAF6. TLRs have been found to heterodimerize with one another, which may also contribute to the repertoire of specificities. It remains to be determined whether differences in adaptor usage and involvement of suppressor molecules can account for the activation of distinct immune responses among the TLRs. It is plausible other unidentified adaptors play a role in TLR signaling or that combinations of adaptor usage provide more distinct signals than those involving individual TIR proteins.

4 Cellular Effector Mechanisms

4.1 Cell-mediated Inflammation

Myeloid cells are critical to the defenses of the innate immune system. These include the monocyte-derived macrophages and dendritic cells and the granulocytic polymorphonuclear neutrophils (PMN), basophils, and eosinophils. These are the first cells to counter infectious processes by internalizing and degrading foreign material. The lymphoid NK cells also play a role in innate immune responses to viral infection.

Macrophages are most concentrated in lymphoreticular organs (the lymph nodes and spleen) but are present throughout the body, forming morphologically distinct populations in different tissues. Tissue histiocytes, osteoclasts, hepatic Küpffer cells, as well as microglial cells of the central nervous system are all considered macrophages. These phagocytic cells survey the blood and connective tissue for potential pathogens. Macrophages are usually the first cell type to encounter pathogen in tissues. Upon encountering a microbe, the cells can engulf and kill it directly, in the process of phagocytosis, or can recruit other myeloid cells, especially PMNs, to the sites of damage or infection. Cytokines secreted by macrophages, including IL-6, 8, and 12 and TNF-α, are all inducers of fever and inflammation associated with an acute-phase response. Secretion of TNF-α and IL-1 alter expression of vascular adhesion molecules such as E-selectin and VCAM-1. The leukocyte CD18 complex integrins allow adhesion to the vascular endothelium. These include CD11a/CD18, LFA-1 and CD11b/CD18, or Mac-1. Interactions mediated by these molecules between the leukocytes and vessel walls allow firm adhesion and diapedesis. Activation of the macrophage by IFNγ and TNF-α from NK cells allow it to kill most intracellular pathogens. Macrophages are also able to present antigens to T-lymphocytes to activate adaptive immune responses and to modulate the type of response by the production of other cytokines. These include secretion of IL-12 for Th1 and IL-10 for Th2 responses. Consequently, macrophages provide one link between innate and specific immunity.

Dendritic cells are specialized phagocytes that are particularly efficient at presenting antigen to T-lymphocytes. Dendritic cells regularly ingest bits of their immediate environment by endocytosis and macropinocytosis. When a pathogen is detected, TLR stimulation and signaling initiates maturation, enabling the DCs to produce costimulatory molecules and enhancing the capacity to present antigen. MHC molecule expression is upregulated and cells proceed to the lymph nodes for T-cell priming. In this way, DCs are poised for activation of adaptive immune responses. Like the macrophages, DCs

take on multiple identities, such as the Langerhans cells of the skin and plasmacytoid cells of the spleen. However, DCs are less numerous than the macrophage.

Polymorphonuclear neutrophils are the most abundant white blood cells in circulation that play a critical role in the destruction of circulating pathogens. These cells are not normally found in tissues but will migrate in response to the release of chemotactic factors by injured tissues or in response to the activation of other cells. At these inflammatory sites, PMNs may become activated and produce large amounts of reactive oxygen species, and release a variety of other toxic products from cytosolic granules. These cells have a short lifetime, spending approximately six hours in circulation, before undergoing apoptosis.

Eosinophils are responsive to cytokines, and themselves produce a variety of chemokines that mediate inflammation. Under normal conditions, these cell types are found in limited numbers, but counts are elevated during parasitic infection and during an allergic adaptive immune response. Most reside in the subepithelium of respiratory, digestive, and urinary tracts. Mast cells reside in nearly all tissues of the body and play major roles in the defense against parasites and in allergic inflammation. Basophils are very similar to mast cells, except that they reside in blood. These cells are distinguishable by large cytoplasmic granules and high-affinity IgE receptors. Degranulation of mast cells and basophils releases histamine, other vasoactive mediators, and certain proinflammatory cytokines, for example, TNF-α and IL-5. These compounds trigger vasodilation and increase vascular permeability, mucus secretion, bronchiolar smooth muscle constriction, leukocyte recruitment, platelet activation, tissue destruction, fever, and pain.

Natural Killer cells migrate in response to chemotactic factors and kill virally infected cells and tumor cells. Binding to target cells is followed by release of perforins into the cell membrane and lysis or stimulation of programmed cell death.

4.2 Oxygen-independent Destruction of Pathogens

Phagocytosis of pathogens occurs following ligation of certain surface receptors on the cell (Fig. 5). Macrophages and neutrophils are highly efficient at phagocytosis, utilizing the external receptors FcR, complement receptors, mannose receptors, and TLRs to mediate binding to foreign or opsonized material. It is an active process involving actin and microtubule restructuring, which surrounds the pathogen with the phagocyte membrane and internalizes it within a phagosome. Intracellular killing takes place when this vesicle is acidified and introduced to lysosomal granules in the macrophage or to azurophil granules in neutrophils, which contain toxic enzymes, proteins, and peptides. Lysosomal proteases and glycolases will disturb parasitic, bacterial, and viral membrane function. Lysozyme does so by cleaving the $\beta-(1-4)$ glycosidic bond within the peptidoglycan of gram-positive bacterial cell walls. Insertion of defensins into pathogen membranes also disrupts membrane permeability. Acid hydrolases and neutral proteinases digest multiple components of bacteria. The antibacterials transferrin and lactoferrin sequesters free iron, thereby preventing the growth of ingested microorganisms.

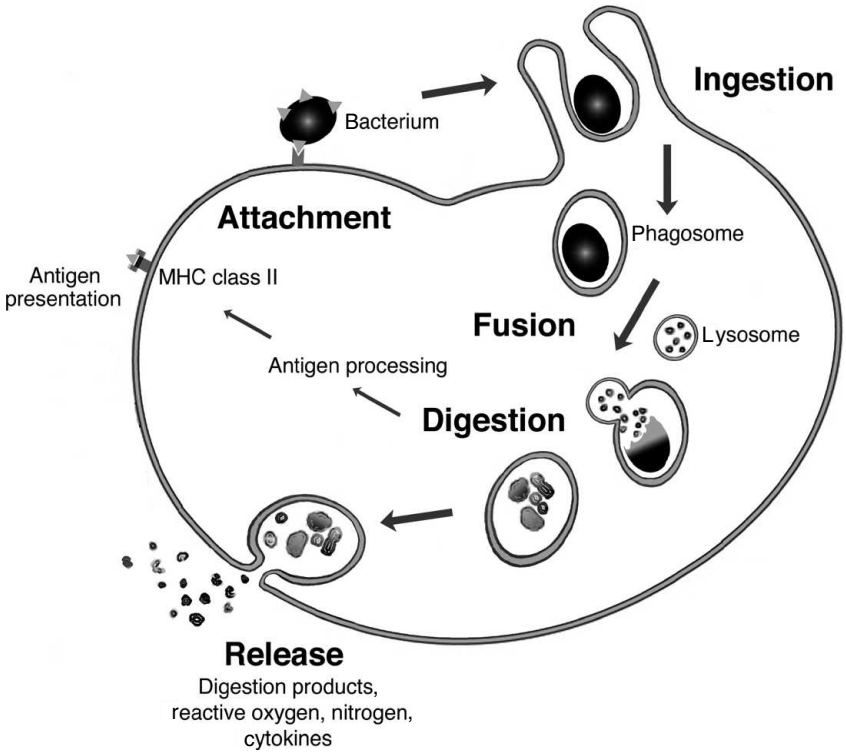

Fig. 5 Processes of phagocytosis. Attachment of the bacterium via FcRs, CRs, TLRs, and other receptors is followed by ingestion of the bacterium, forming a phagosome. Acidification of the phagosome and fusion with the lysosome allows toxic products to kill microbes and proteolytic enzymes to digest the ingested material. Release of digestion products from the cell is accompanied by antigen presentation and release of effectors.

While azurophil granules function predominantly intracellularly within the phagolysosomal vacuole, neutrophil-specific granules are prone to release their contents to the extracellular milieu and appear to have a significant role in the initiation of inflammation.

4.3 Oxygen-dependent Killing

Phagocytes may also undergo a respiratory burst to help kill engulfed microorganisms. This involves a reduction and metabolism of oxygen by cellular enzymes to superoxide ($O_2^{\bullet -}$) and hydrogen peroxide (H_2O_2), ultimately forming toxic products such as hypohalous acid (HOCl/HOBr) and hydroxyl radical (•OH). Subunits of the enzyme NADPH oxidase assemble in the phagosomal and cellular membranes in response to neutrophil activation. This activation arises from the interaction between opsonized particles or pathogens and neutrophil receptors. The phagocyte oxidase transfers electrons from NADPH to oxygen, forming superoxide anion (Eq. 1). Superoxide may spontaneously dismutate or

the enzyme superoxide dismutase may catalyze the formation of H_2O_2 and ground state O_2 (Eq. 2). Myeloperoxidase in neutrophil azurophilic granules catalyzes the formation of HOCl from H_2O_2 and chloride ions (Eq. 3). In the same manner, brominated species may also be formed, however, at much lower concentrations.

$$2O_2 + \mathrm{NADPH} \longrightarrow 2O_2{\bullet}^- + \mathrm{NADP}^+ + H^+ \quad (1)$$

$$2H^+ + 2O_2{\bullet}^- \longrightarrow 2H_2O_2 + O_2 \quad (2)$$

$$X^- + H_2O_2 + H^+ \longrightarrow HOX + H_2O \qquad X = \mathrm{Cl, Br} \quad (3)$$

Superoxide ion, hydrogen peroxide, and hypochlorite are all efficient oxidizing agents that can kill bacteria and fungi by oxidizing membrane lipids and proteins. Further reactions of these oxidants catalyzed by transition metals can produce •OH (Eq. 4). Hydroxyl radical is the most biologically reactive of the aforementioned oxidants. Singlet oxygen ($^1O_2$) is an excited state of dioxygen that debatably forms downstream of HOCl or •OH, which has deleterious effects on macromolecules (Eqs. 5 and 6).

$$O_2{\bullet}^- + \mathrm{HOCl} \longrightarrow O_2{\bullet}^- + {\bullet}\mathrm{OH} + \mathrm{Cl}^- \quad (4)$$

$$\mathrm{OCl}^- + H_2O_2 \longrightarrow {}^1O_2 + \mathrm{Cl}^- + H_2O \quad (5)$$

$$O_2{\bullet}^- + {\bullet}\mathrm{OH} \longrightarrow {}^1O_2 + \mathrm{HO}^- \quad (6)$$

Singlet oxygen is also thought to be formed during the dismutation of peroxyl radical and during the decomposition of 1,2-hydroperoxides. The presence of $^1O_2$ during the oxidative burst provides a means by which the proposed oxidation of water by antibodies that has been postulated leads to trioxygen species generation (Eq. 7).

$$x^1O_2 + yH_2O \longrightarrow [H_2O_3(y-1)H_2O] \longrightarrow O_3 + H_2O_2 + (x-1)O_2 \quad (7)$$

While this reaction has mainly been characterized as a function of antibodies, other immunoglobulin fold-containing proteins may also catalyze the process. Its contribution to innate defenses and immunity as a whole has not yet been fully elucidated. The reactive oxygen species produced by activated phagocytes act in concert to effect microbial killing. Reactive nitrogen species such as nitric oxide (NO) and peroxynitrite ($OONO^-$) are also important for immune defense in that they mediate intercellular signaling and are also toxic to bacteria.

5 Humoral Effector Mechanisms

5.1 Complement

The complement system is a component of innate immunity concerned with the lysis and clearance of foreign particles and host debris. Activation of this system involves binding and cleavage of multiple proteins and glycoproteins, both soluble and membrane bound. The formation of active enzyme complexes and deposition of proteolytic fragments in this process recruits phagocytes to sites of infection, prompts direct cell lysis, and opsonizes pathogens for phagocytosis. Induction of inflammatory mediators also occurs as a result of complement activation (Fig. 6).

Complement enzyme precursors are activated locally and initiate inflammatory events in response to specific stimuli such

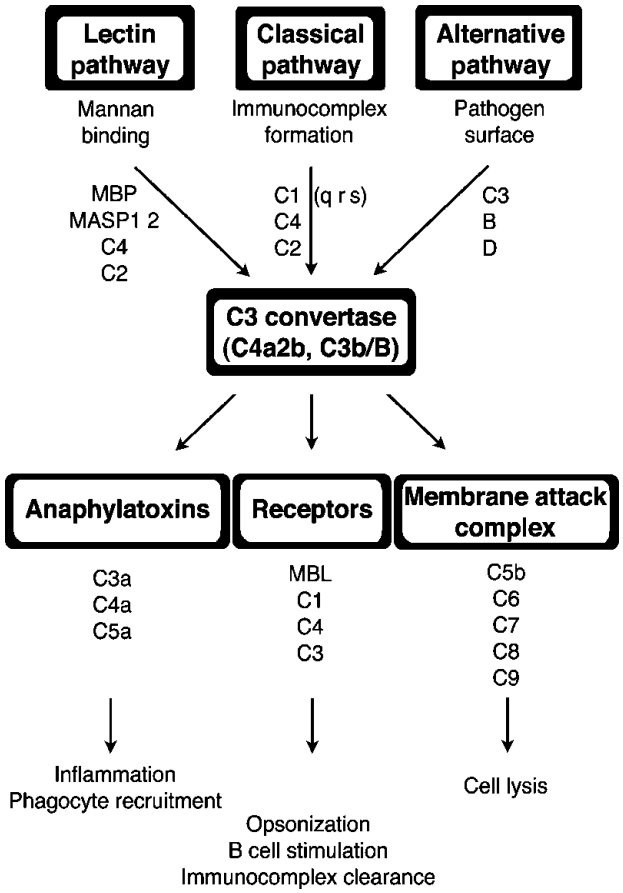

Fig. 6 Complement pathways and proteins. Complement regulatory proteins not shown include C1INH, C4bp, CR1, MCP, DAF, H, I, P, and CD59.

as pathogen binding and immunocomplex formation. This may occur by three pathways. In the classical activation pathway, the pentameric protein complex C1, made up of a C1q subunit and two subunits each of C1r and C1s, binds directly to pathogens or to antibodies that are in complex with pathogens. In the latter case, C1 links adaptive immunity to the innate complement system. Proteolytic cleavage of C1r and C1s activates C1 to sequentially cleave other complement proteins (C4 then C2) to form an active C3 convertase (C4b2a). The mannan-binding lectin pathway uses a similar route to form an identical C3 convertase: serum PRRs bind mannose residues on bacterial or viral carbohydrates, forming an MBL/MASP complex, to activate complement proteins C4 and C2 and to form an active C3 convertase. Finally, alternative activation occurs when complement component C3 becomes spontaneously activated, for example, by microbial compounds LPS or

LTA, and gets deposited onto the surface of a pathogen. Properdin is a positive regulator of the alternative pathway of complement activation, released by peripheral blood cells and the endothelium. Binding and cleavage of plasma factor B produces a fluid-phase C3 convertase.

The C3 convertases cleave C3 to produce C3a, an anaphylactic by-product that mediates inflammatory responses, and C3b, which acts as an opsonin for phagocytes with complement receptors. C3b also activates a C5 convertase, thereby producing C5a, an important inflammatory mediator, and C5b, which initiates late events of complement. These entail polymerization of the terminal complement components, C6 to C9, to form porelike membrane attack complexes (MACs), leading to loss of bacterial cell integrity and lysis. Phagocyte ingestion of complement-opsonized pathogens is mediated by specific complement receptors. There are five known types of complement receptors. The receptor for C3 (CR1) is present on neutrophils and macrophages and can promote binding and phagocytosis.

The complement system is efficient in the defense against many viral and bacterial infections as well as in the removal of cellular debris. However, if improperly regulated, complement can cause severe host tissue damage, as in rheumatoid arthritis, acute hemolytic anemia, or glomerulonephritis. Other conditions including mechanical injury and myocardial infarction can stimulate inopportune complement-mediated damage as well.

5.2 Antimicrobial Peptides

Cationic antimicrobial peptides produced by vertebrates, arthropods, plants, insects, and bacteria are small stretches of less than 50 amino acids that possess activity against bacteria, fungi, and protozoa. Of the more than 800 antimicrobial peptides submitted in the Antimicrobial Sequences Database (http://www.bbcm.univ.trieste.it/~tossi/amsdb.html), over 175 are produced by insects. These peptides are particularly important in the immune defenses of the well-studied fruit fly, *Drosophila melanogaster*. Proteins include the antibacterials Andropin, Attacin, Cecropin, Diptericin (gram negative), Defensin (gram positive), and Drosocin; and the antifungals Drosomycin and Metchnikowin, among many others. The genes encoding most of these protein effectors are induced in response to infection and the peptides secreted from *Drosophila* fat bodies. Andropin is the exception to the rule in that it is constitutively expressed in males. In contrast, most mammalian antimicrobial proteins, including the cryptidins or α-defensins present in the intestines and β-defensins produced in the skin and respiratory tract, are ubiquitously produced as part of innate constitutive defenses.

Two general mechanisms of action of these molecules have been indicated and segregated on the basis of being either membrane disruptive or nonmembrane disruptive. Initial associations of these peptides with microbes occur through electrostatic interactions, for example, between the peptide and negatively charged LPS in bacterial cell membranes. Destabilization of the outer membrane creates sites on the cytoplasmic membrane that are more susceptible to translocation or membrane disruption. It is postulated that transient pores are formed by the peptide that span the membrane, resulting in membrane depolarization and disintegration. Alternatively,

peptides may form micellar aggregates in the outer leaflet, which collapse allowing translocation into the cytoplasm. Inside the bacterium, peptides interact with nucleic acids and cellular proteins, inducing transcriptional changes and inhibiting further synthesis of macromolecules.

The peptides are classified on the basis of secondary structure into four major classes: β-sheet, α-helix, loop, or extended peptides (Fig. 7). The majority of known peptides belong to the first two groups, according to circular dichroism spectroscopy. High-resolution structures of these peptides, obtained by 2-d ^{1}H NMR, exist for about 50 of these molecules. The α-helical antimicrobials are characterized by an α-helical conformation containing a slight bend in the center of the molecule. This bend may be crucial for suppressing undesirable hemolytic activity. Structure–activity studies of magainin *2*, a typical α-helical peptide, suggest no difference in D- and L-enantiomers, ruling out chiral receptors or enzyme targets

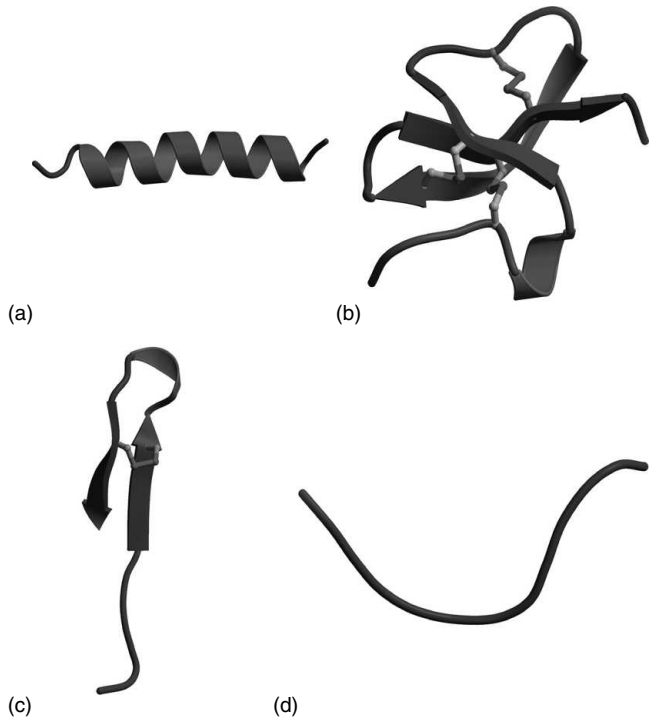

Fig. 7 Antimicrobial peptides. Representative member of each structural class: (a) magainin 2, alpha-helix; (b) β-defensin, beta-sheet; (c) thanatin, loop; (d) indolicidin, extended. Pictures generated by Matt Kelker, using bobscript and raster3D. Coordinates obtained from the RCSB Protein Data Bank under the accession codes 1BNB (defensin), 1G89 (indolicidin), 2MAG (magainin), and 8TFV (thanatin). Raster3D: Merritt & Bacon (1997) *Meth. Enzymol.* **277**, 505–524. bobscript: Esnouf, RM (1997) *J. Mol. Graph. Model.* **132–134**, 112–113.

as mechanisms of action. Furthermore, an increase in cationic charge, up to +5, leads to an increase in antimicrobial activity. This is presumably due to enhanced association with the negatively charged cell surface. Peptides containing antiparallel β-sheets, such as tachyplesin, disrupt lipid organization and undergo membrane translocation. Stabilizing disulfide bonds within the structure suggest that flexibility is pertinent for translocation to occur. The class of peptides with extended conformations are high in proline or glycine content and hence lack overall secondary structure. These extended peptides tend to form hydrogen bonds and Van der Waals interactions with membrane lipids. Evidence exists that extended peptides, such as indolicidin, translocate into the cytoplasm to inhibit DNA synthesis; however, the mechanism has not been explicitly determined. Finally, loop peptides such as the insect antimicrobial thanatin contain a single disulfide, amide, or isopeptide bond. The exact mechanism of killing by thanatin is unknown, but the molecule evidently does not perturb membrane permeability. The antimicrobial mechanism appears to be target specific, as only L-thanatin

Tab. 3 Effects of cytokines on the innate immune system.

Cytokine	*Origin*	*Function*
IL-1α and -1β	Monocytes, macrophages, epithelium, endothelium, fibroblasts	costimulation of APCs and T cells, inflammation, adhesion and fever, acute-phase response
IL-2	NK cells, activated TH_1 cells	proliferation of B cells and activated T cells, NK functions
IL-4	Mast cells, basophils TH_2 cells	B-cell proliferation, eosinophil and mast-cell growth and function, IgE and class-II MHC expression on B cells, inhibition of monokine production
IL-5	TH_2 and mast cells	B-cell and eosinophil growth and function
IL-6	Activated TH_2 cells, monocytes, macrophages, epithelium, endothelium	acute-phase response, B-cell proliferation, thrombopoiesis, synergistic with IL-1 and TNF-α
IL-8	Monocytes, macrophages, epithelium	chemoattractant for neutrophils and T cells
IL-10	Macrophages, activated TH_2 cells, CD8+ B cells	inhibits cytokine production (IL-1, -2 and TNF-α), promotes B-cell proliferation and antibody production, suppresses cellular immunity, mast-cell growth
IL-12	Monocytes, macrophages	NK and TH_1 cell activation
IFN-α and -β	DCs, epithelium, fibroblasts	Antiviral, increases MHC I expression, suppresses proliferation
IFN-γ	Macrophages, NK cells, activated TH_1 cells	Antiviral, increases MHC I &II expression, suppresses proliferation
TNF-α	Macrophages, NK cells, mast cells, epithelium	Phagocyte activation, fever, antitumor activity
G-CSF, M-CSF, GM-CSF	Various	Growth and maturation of PMNs and monocytes

is effective against gram-negative bacteria but both enantiomeric forms of the peptides possess activity against gram-positive and fungal species.

Cationic charge and amphipathic conformation appear to be the greatest requirements for antimicrobial activity. Significantly, components of the target membrane may also determine the efficacy of these peptides. Further study of peptide–membrane interactions may explain activity of these molecules with individual organisms.

5.3 Cytokines

Whereas peptides seem to predominate in the immune defenses of insects, cytokine-mediated inflammation is highly significant in mammals. Cytokines are primarily secreted by leukocytes, stimulating both humoral and cellular immune responses as well as activation of phagocytosis (Table 3). The proinflammatory cytokines TNF-α, IL-1, and IL-6, and chemokines such as IL-8 are released in response to encounters with pathogens, specifically by PAMP/PRR interactions. TNF-α is the primary mediator of acute inflammation, and the interleukins enhance this action by increasing endothelial adhesion, increasing chemokine secretion, activating cell-mediated immunity, and stimulating hepatocytes to secrete acute-phase proteins. Type-I interferons produced by virus-infected cells inhibit viral replication and kill infected cells by degrading mRNA. Interferons also activate TH_1 cells, which activate cytotoxic T cells and NK cells, which kill pathogens.

Keywords

Avidin
A tetrameric glycoprotein found in chicken egg white, which specifically binds biotin with an extremely high affinity ($K_d \sim 10^{-15}$ M) (see also Streptavidin below).

Biotin
A water-soluble vitamin (vitamin H) that can be incorporated relatively easily into various biological materials.

Biotinylation
The incorporation of biotin or its derivatives into biological material.

Protein A
A cell wall protein of *Staphylococcus aureus*, which specifically binds the Fc domain of an immunoglobulin G molecule without disturbing its antigen-binding ability.

Streptavidin
A tetrameric nonglycosylated protein produced by *Streptomyces avidinii*, which specifically binds biotin with an extremely high affinity ($K_d \sim 10^{-15}$ M).

Immuno-PCR is an antigen detection system, in which the polymerase chain reaction (PCR) is used to amplify a segment of marker DNA that has been attached specifically to antigen–antibody complexes. Because of the enormous amplification capability and specificity of PCR, immuno-PCR allows considerable enhancement in detection sensitivity of a specific antigen over conventional antigen detection systems, such as enzyme-linked immunosorbent assays and radioimmunoassays. A variety of superior characteristics and the versatility of immuno-PCR, including high but controllable sensitivity, simplicity, and easy contamination control, offer great promise for its application in various aspects of biological and medical sciences, as well as clinical diagnostics and forensic medicine.

1 Concept

The concept of immuno-PCR (polymerase chain reaction), illustrated in Fig. 1, is quite simple, and is similar to those of conventional antibody-based antigen detection systems, such as enzyme-linked immunosorbent assays (ELISA) and radioimmunoassays (RIA).

In the original immuno-PCR scheme, a molecular linker, which has a bispecific binding affinity for antibody and DNA, is used to attach a marker DNA molecule specifically to an antigen–antibody complex. A segment of the attached marker DNA is amplified by PCR with appropriate primers, and the resulting PCR products are analyzed. The presence of specific PCR

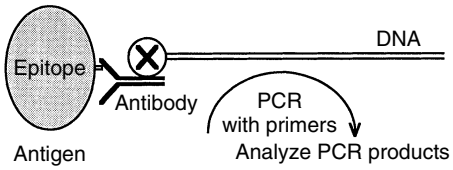

Fig. 1 Concept of immuno-PCR. See Sect. 1 for explanation. [Reprinted, with permission, from Sano, *Cell Technol.* **13**:77–80 (1994)].

products demonstrates that the marker DNA molecules are attached specifically to antigen–antibody complexes, indicating the presence of antigen.

2 Reagents

2.1 Molecular Linkers between Antibody and Marker DNA

In conventional antigen detection systems, secondary antibodies, directed against a primary antibody, are generally used to attach labels, such as reporter enzymes in ELISA or radioactive labels in RIA, to complexes between antigen and primary antibodies. In contrast, immuno-PCR uses specific molecular linkers to attach marker DNA specifically to antigen–antibody complexes. Thus, such molecular linkers are key components in immuno-PCR.

Molecular linkers used in immuno-PCR must possess bispecific binding affinity for antibody and DNA to attach marker DNA specifically to antigen–antibody complexes.

One unique and particularly versatile molecular linker for immuno-PCR is a streptavidin-protein A chimera. This streptavidin-protein A chimera was designed by genetic engineering of the streptavidin and protein A genes, which were isolated from *Staphylococcus aureus* and *Streptomyces avidinii*, respectively. A part of the protein A gene encoding two IgG-binding domains was fused to a modified streptavidin gene. The gene fusion can be expressed in *Escherichia coli* by using the T7 expression system, and the expressed streptavidin-protein A chimera can be purified to homogeneity by a simple purification procedure. This chimera possesses two independent binding abilities; one is to biotin, derived from the streptavidin moiety, and the other is to the Fc domain of an immunoglobulin G (IgG) molecule, derived from the protein A moiety. The chimera forms a subunit tetramer, which binds four biotins and four IgG molecules. This bifunctional multivalent binding specificity for biotin and antibody allows the specific conjugation of any biotinylated DNA molecule to antigen–antibody complexes.

Other simple, yet very useful molecular linkers, which can be used in immuno-PCR, are monospecific, multivalent binding molecules, such as streptavidin and avidin, each molecule of which can bind up to four biotins. Although these proteins do not bind antibody and biotinylated marker DNA independently, biotinylated marker DNA can be attached to antigen–antibody complexes by the use of biotinylated antibodies. In these methods, the biotinylated antibody is first bound to antigen (formation of complexes between antigen and biotinylated antibody). Then, streptavidin or avidin is directed to biotin conjugated to the antibody (formation of complexes consisting of antigen, biotinylated antibody, and streptavidin or avidin). Finally, biotinylated marker DNA is directed to

free biotin-binding sites of streptavidin or avidin molecules that have been attached to complexes between the antigen and the biotinylated antibody. This is followed by amplification of a segment of bound biotinylated marker DNA by PCR.

Specific chemical conjugates of antibody with marker DNA can also be used in immuno-PCR without the need for molecular linkers. Such chemical conjugates can be produced by attaching derivatized DNA molecules covalently to antibody molecules. Such chemical conjugates between antibody and marker DNA should be very useful for large-scale analysis of selected antigens, such as in clinical diagnostics, since they can be produced in large quantities and stored until used. However, because of laboriousness of many chemical conjugation procedures and the need for purification of functional conjugates, the overall versatility of performance of immuno-PCR could be reduced, limiting their use in certain settings where a number of different antigens need to be analyzed.

2.2 Antibodies

Both monoclonal and polyclonal antibodies can be used in immuno-PCR. In addition, genetically engineered antibodies, including single-chain antibodies, can also be used. When the streptavidin-protein A chimera is used as a molecular linker between antibody and marker DNA, the antibodies used must have the Fc portion, to which the protein A moiety of the streptavidin-protein A chimera can bind. The Fc portion of certain IgG subclasses does not have sufficient binding affinity for protein A. For example, mouse IgG_1, sheep immunoglobulins, and horse immunoglobulins have only very low affinity for protein A. These antibodies cannot be used directly in immuno-PCR with the streptavidin-protein A chimera as a molecular linker between primary antibody and biotinylated marker DNA. However, such antibodies can be used indirectly by letting them serve as targets for secondary antibodies, which have high binding affinity for protein A, directed against the primary antibodies.

Because of the extremely high sensitivity of immuno-PCR, very low concentrations of antibody are generally used. For example, the concentration of primary antibody can be diluted by several orders of magnitude below those used in conventional ELISA. For given antigen samples and antibody preparations, optimal concentrations of antibody, where the highest sensitivity and signal-to-noise ratios are obtained, should be determined by calibration using different concentrations of antibody.

2.3 Marker DNA

Marker DNA used in immuno-PCR is purely arbitrary. Therefore, any DNA molecules can be used unless their amplified regions are contained in sample-derived nucleic acids.

The marker DNA used most frequently in immuno-PCR is the end-biotinylated linear DNA molecule. Incorporation of multiple biotins into a marker DNA molecule should be avoided. Since molecular linkers used in immuno-PCR are generally multivalent, conjugation of marker DNA containing multiple biotins to linker molecules causes aggregation, resulting in the generation of background signals.

Conventionally, plasmid DNA is used to prepare marker DNA. The use of plasmid

DNA offers ease in handling and manipulations. Purified plasmid DNA is digested with two or more restriction endonucleases. Biotin is incorporated into one of the termini of the linear plasmid DNA by filling-in reactions with a template-dependent DNA polymerase in the presence of a biotin-labeled deoxynucleotide, such as biotin-dATP. Generally, Klenow fragment of *E. coli* DNA polymerase I or T7 DNA polymerase and its derivatives are used. Because all four deoxynucleotides containing biotin are available, restriction endonuclease digestion sites, where biotin can be incorporated, can be chosen with great flexibility. After the incorporation of biotin, the resulting end-biotinylated marker DNA should be purified by an appropriate method to remove unincorporated biotin-labeled deoxynucleotides. This step is important to avoid the binding of unincorporated biotin-labeled deoxynucleotides to the streptavidin moiety of the streptavidin-protein A chimera, streptavidin, or avidin, which serves as a molecular linker.

Another simple, efficient method to prepare an end-biotinylated marker DNA is PCR with a biotinylated primer. A segment of a template DNA is amplified by PCR with a set of primers, a biotinylated primer and a nonbiotinylated primer. In this way, it is important to remove unincorporated biotinylated primers to avoid the binding of the biotinylated primers to the streptavidin moiety of the streptavidin-protein A chimera, streptavidin, or avidin, which is used as a molecular linker. In addition, primer dimers containing biotin, if any, should also be removed.

The efficiency of biotinylation of marker DNA can be estimated by simple gel retardation assays. End-biotinylated marker DNA is mixed with streptavidin or avidin at various ratios. Each of the resulting mixtures is separated by conventional agarose gel electrophoresis. In the presence of excess amounts of streptavidin or avidin, retardation of end-biotinylated marker DNA, which results from the binding of streptavidin or avidin, can be seen. Marker DNAs as large as several kilobase pairs can be analyzed by this method. Larger marker DNAs would not be suitable for immuno-PCR. By using one of the two biotinylation methods described above, the efficiency of biotinylation should be very close to 100%.

End-biotinylated marker DNAs generated by one of the above methods are very stable, and can be stored in a frozen state for many months.

2.4 Conjugation of Marker DNA to Molecular Linkers

Conjugation of end-biotinylated marker DNA to the streptavidin-protein A chimera, used as a molecular linker, can be performed by simply mixing the two components (the chimera and end-biotinylated marker DNA) at a molar ratio of biotin to biotin-binding site of 1 or below. Because of the extremely high affinity of the streptavidin moiety of the streptavidin-protein A chimera for biotin, few unconjugated end-biotinylated marker DNA molecules should be present. The resulting conjugate will contain up to four end-biotinylated marker DNA molecules per chimera molecule.

When streptavidin or avidin is used as a molecular linker, end-biotinylated marker DNA is generally not conjugated to streptavidin or avidin prior to analysis. Instead, streptavidin or avidin, and end-biotinylated marker DNA are applied sequentially during analysis to direct the marker DNA to unoccupied biotin-binding

sites of streptavidin or avidin that has been bound to biotinylated antibody. This allows *in situ* formation of complexes consisting of biotinylated antibody, (strept)avidin, and marker DNA on antigens. Preconjugation of end-biotinylated marker DNA to streptavidin or avidin prior to analysis is possible. However, end-biotinylated marker DNA must be attached to streptavidin or avidin under saturation, since the resulting conjugates must have free biotin-binding sites for their binding to biotinylated antibodies.

3 Methods

There are several formats of immuno-PCR. One of the most versatile ways to perform immuno-PCR uses microtiter plates as solid supports, which allow simultaneous analysis of large numbers of samples. A few representative immuno-PCR formats using the streptavidin-protein A chimera as a molecular linker between antibody and biotinylated marker DNA are described, along with brief descriptions of the modification of the procedures when streptavidin or avidin is used as a molecular linker and when chemical conjugates of antibody with marker DNA is used.

3.1 Basic Microtiter Plate Format

In the microtiter format, antigen is immobilized directly on the surface of microtiter plate wells. The protocol for the detection of antigen immobilized on microtiter plate wells, illustrated schematically in Fig. 2, consists of six steps:

Step 1: immobilization of antigen on the surface of the microtiter plate wells;
Step 2: blocking of free binding sites on the well surfaces with appropriate blockers;
Step 3: binding of antibody to antigen;
Step 4: binding of the streptavidin-protein A chimera, bound to end-biotinylated marker DNA, to antigen–antibody complexes;
Step 5: amplification of a segment of the marker DNA by PCR with appropriate primers; and
Step 6: analysis of PCR products.

The key factor in this protocol is the efficient and complete removal of unbound and nonspecifically bound antibody and marker DNA, which contribute to background signals. Therefore, extensive washing must be carried out after each step. One of the advantages of the use of microtiter plates as a solid support is that washing steps can be performed quite easily even with large numbers of samples.

When streptavidin or avidin is used as a molecular linker, the above procedure is slightly modified. The primary antibody is biotinylated, as described in Sect. 2.2, prior to its application to antigen-containing samples immobilized on the surface of the microtiter plate wells. Step 4, where the streptavidin-protein A chimera containing end-biotinylated marker DNA is applied to antigen-containing samples immobilized on the surface of the microtiter plate wells, is divided into two steps. The first step is the application of streptavidin or avidin to samples. After unbound streptavidin or avidin molecules are removed, end-biotinylated marker DNA is directed to unoccupied biotin-binding sites of streptavidin or avidin molecules that have been bound to biotinylated antibody.

When chemical conjugates of antibody with marker DNA are used, the above

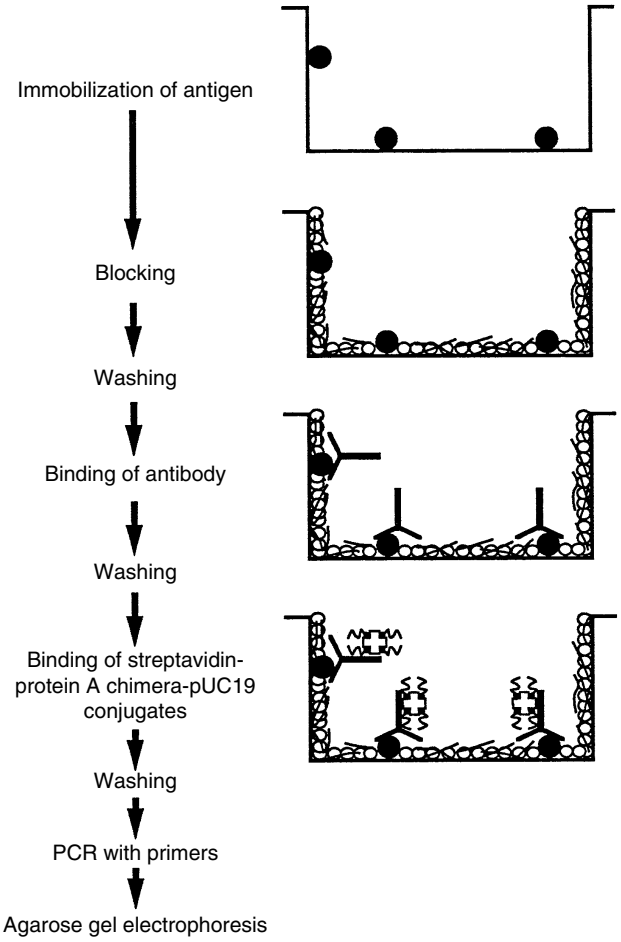

Fig. 2 Schematic illustration of basic microtiter plate format of immuno-PCR. [Reprinted, with permission, from Sano, *Cell Technol.* **13**:77–80 (1994)].

procedure is simplified. Instead of applying antibody and the streptavidin-protein A chimera containing end-biotinylated marker DNA sequentially (Steps 3 and 4), the chemical conjugates can be added to samples in one step, followed by the removal of unbound conjugates and the amplification of a segment of the marker DNA.

An example of the detection of antigen using the basic microtiter plate format with the streptavidin-protein A chimera as a molecular linker is shown in Figs. 3 and 4. In this system, bovine serum albumin (BSA) was used as antigen, and mouse monoclonal antibody (subclass, IgG_{2a}) against BSA was directed to the immobilized antigen. By using 30 amplification cycles in the PCR step, as few as 580 molecules (9.6×10^{-22} mol) of antigen were specifically and reproducibly detected. Direct comparison of

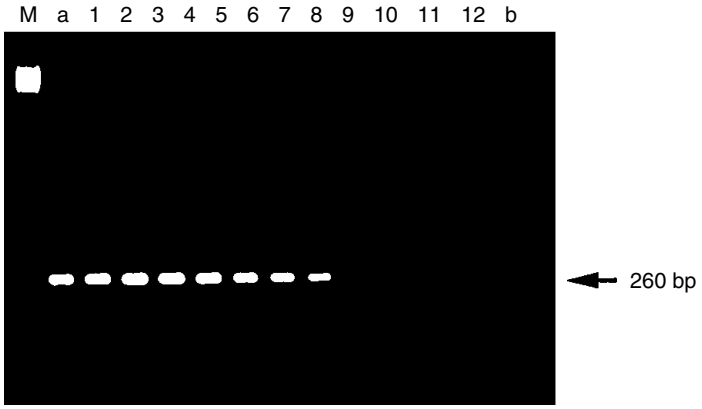

Fig. 3 Detection of BSA immobilized on a microtiter plate by immuno-PCR. Immobilized BSA was detected by immuno-PCR using monoclonal anti-BSA and a streptavidin-protein A chimera containing a 2.67-kb end-biotinylated linear plasmid as a marker. A 260-bp segment of the marker DNA was amplified by PCR, and the resulting PCR products were analyzed by agarose gel electrophoresis, stained with ethidium bromide. Lanes 1 to 9 contain PCR amplification mixtures with immobilized antigen: Lane 1, 96 fmol (5.8×10^{10} molecules); 2, 9.6 fmol (5.8×10^{9} molecules); 3, 960 amol (5.8×10^{8} molecules); 4, 96 amol (5.8×10^{7} molecules); 5, 9.6 amol (5.8×10^{6} molecules); 6, 0.96 amol (5.8×10^{5} molecules); 7, 9.6×10^{-20} mol (5.8×10^{4} molecules); 8, 9.6×10^{-21} mol (5.8×10^{3} molecules); 9, 9.6×10^{-22} mol (5.8×10^{2} molecules). Lanes 10 to 12 are derived from control wells, where no antigen was immobilized. [Reprinted, with permission, from Sano, T., Smith, C.L., Cantor, C.R. (1992) Immuno-PCR: Very sensitive antigen detection by means of specific antibody-DNA conjugates, *Science* **258**, 120–122.]

a conventional antigen detection system, ELISA, using alkaline phosphatase as a reporter enzyme indicated approximately 10^5 times enhancement in detection sensitivity was obtained by using immuno-PCR.

There are several key factors that determine the overall sensitivity and signal-to-noise ratios for given antigen samples and antibody preparations. Generally, optimization of these factors is carried out by empirical methods. The use of the microtiter plate format greatly facilitates this optimization step, because many samples can be easily analyzed simultaneously.

3.2 Sandwich Assay Format

The basic microtiter plate format, described in Sect. 3.1, is likely to generate high background signals when the antigen in physiological fluids containing endogenous immunoglobulins, such as blood samples, is to be detected and the streptavidin-protein A chimera is used as a molecular linker between the antibody and marker DNA. This occurs because of the binding of the protein A moiety of the streptavidin-protein A chimera to sample-derived immunoglobulins.

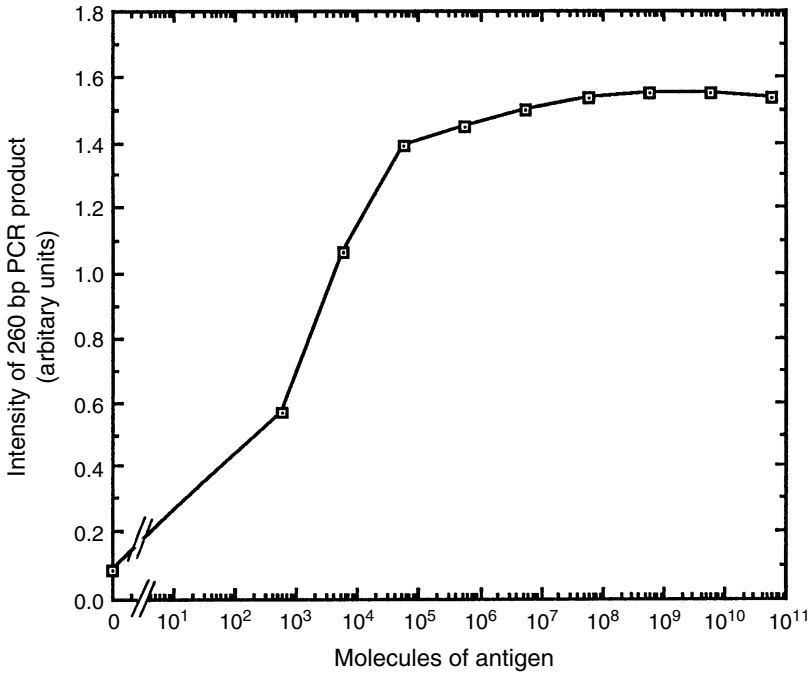

Fig. 4 Quantitation of PCR product generated by immuno-PCR. The 260-bp PCR fragment shown in Fig. 2 was quantitated, and plotted as a function of the number of antigens. Note that PCR amplification was not saturated in a range from 10^2 to 10^5 molecules of antigen, where the number of antigen molecules can be estimated. [Reprinted, with permission, from Sano, T., Smith, C.L., Cantor, C.R. (1992) Immuno-PCR: Very sensitive antigen detection by means of specific antibody-DNA conjugates, *Science* **258**, 120–122.]

One format that can be used for the detection of antigen in immunoglobulin-containing samples using the streptavidin-protein A chimera as a molecular linker is sandwich assays. In this sandwich assay format, the antigen is captured by immobilized binding molecules, which have high binding affinity for the antigen. For example, immobilized primary antibody fragments, such as Fab and $F(ab')_2$, which lack the Fc portion and, thus, do not have binding affinity for protein A, can be used to capture a specific antigen (see Fig. 5). This step allows the purification of specific antigen, thereby removing sample-derived immunoglobulins and other nonantigen molecules. Subsequently, the basic immuno-PCR procedure, described in Sect. 3.1, can be used to detect the captured antigen. To maximize the binding of the secondary antibody to the captured antigen, polyclonal antibodies are used as the secondary antibody. Monoclonal antibodies can also be used as the secondary antibody if the binding of secondary antibodies to captured antigens is inhibited or considerably disturbed by immobilized primary antibodies.

Another attractive, yet universal group of molecules to capture specific antigen is mouse monoclonal antibodies of subclass IgG_1. Antigen can be specifically captured

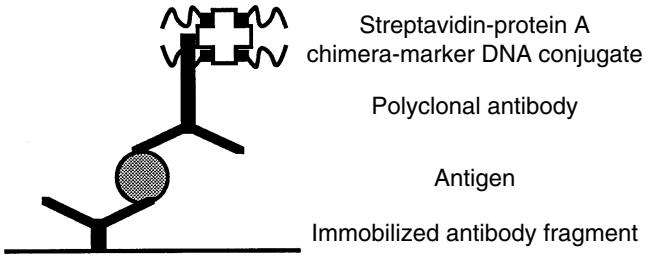

Fig. 5 Schematic illustration of sandwich assay format. In this example, antigen is captured by primary antibody fragments immobilized on a solid support. *See* Sect. 3.2 for explanation.

by immobilized mouse monoclonal antibodies, and then sample-derived immunoglobulins can be removed by washing. Mouse IgG_1 has very low affinity for protein A. Therefore, the binding of the protein A moiety of the streptavidin-protein A chimera to mouse IgG_1 monoclonal antibodies immobilized on a solid support is ignorable. Because many of the monoclonal antibodies available are mouse IgG_1, this format provides greater versatility in the detection of various biological molecules by immuno-PCR.

If specific binding molecules to antigen are available, such molecules can also be immobilized to capture antigen, thereby removing sample-derived immunoglobulins. Such binding molecules include ligands, receptors, and cofactors. For example, ligand molecules can be specifically captured by immobilized receptor molecules of this ligand, and thus sample-derived immunoglobulins can be removed by washing. Then the captured ligand can be detected by the basic immuno-PCR procedure, described in Sect. 3.1, with the use of polyclonal antibodies against the ligand.

When streptavidin or avidin is used as a molecular linker between the antibody and biotinylated marker DNA or when chemical conjugates of antibody with marker DNA is used, the presence of endogenous immunoglobulins in samples should, in principle, pose little problem since these molecules have no apparent binding affinity for immunoglobulins. However, the sandwich assay format often offers greater specificity and higher signal-to-noise ratios, as seen with ELISA, because of the removal of nontarget molecules from samples prior to the application of antibody and marker DNA.

3.3 Preconjugation Format

An attractive alternative method for the detection of antigen in immunoglobulin-containing samples is to preconjugate antibody and end-biotinylated marker DNA to the streptavidin-protein A chimera prior to the application to samples (preconjugation format) (Fig. 6). This is very similar to chemical conjugates of antibody with marker DNA. Because the streptavidin-protein A chimera binds both biotin and IgG stoichiometrically, specific conjugates, consisting of the streptavidin-protein A chimera, antibody, and end-biotinylated marker DNA, can be produced by simply mixing the three components in the appropriate ratios. By using an appropriate mixing ratio of antibody to the streptavidin-protein A chimera, the IgG-binding domain of the protein A moiety of

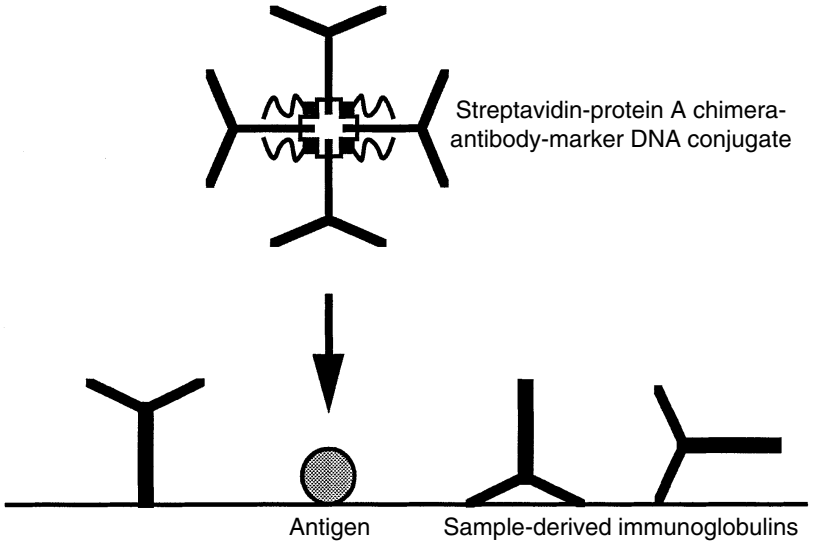

Fig. 6 Schematic illustration of preconjugation format. A specific conjugate, consisting of the streptavidin-protein A chimera, antibody, and end-biotinylated marker DNA, is applied to antigen in an immunoglobulin-containing sample. See Sect. 3.3 for explanation.

the chimera can be saturated. Such conjugates should not bind to immunoglobulins present in samples, because of saturation of the IgG-binding sites with antibodies. In addition, few exchange reactions should occur during a short period of time used in this type of assay, because of the high binding affinity of protein A for antibodies.

In the basic microtiter plate format, described in Sect. 3.1, antibodies and the streptavidin-protein A chimera containing end-biotinylated marker DNA are applied to samples sequentially. In the preconjugation format, specific conjugates consisting of the chimera, antibodies, and end-biotinylated marker DNA, are applied to samples at one time (Fig. 6). Therefore, an additional advantage of the preconjugation format is that the number of steps in a protocol can be reduced. In general, procedures with fewer steps are particularly useful to analyze large numbers of samples simultaneously, such as in clinical diagnostics. In addition, such procedures should facilitate the development of fully automated immuno-PCR assay systems.

3.4 Other Formats

With simple modifications of the protocols described above, several other immuno-PCR formats are available without loss in detection sensitivity. One of these is the combination of the sandwich assay format and the preconjugation format, for example, by using immobilized primary antibody fragments, a specific antigen can be captured and purified. Then, specific conjugates, consisting of the streptavidin-protein A chimera, antibody, and end-biotinylated marker DNA, are applied to the captured antigen. This format not only

allows the specific detection of antigen in immunoglobulin-containing samples but it can also reduce the number of steps in a protocol.

Another attractive solid support that can be used in immuno-PCR is paramagnetic microbeads (or nanoparticles). Paramagnetic microbeads are available with surfaces coated covalently with binding molecules, such as antibodies and streptavidin. Because paramagnetic microbeads can be separated and transferred by the application of magnetic fields, the use of paramagnetic microbeads in immuno-PCR should greatly facilitate the manipulation of samples during analysis.

Another simple, yet attractive format would be the detection of antigen molecules on cell surfaces by immuno-PCR (cell surface immuno-PCR). Centrifugation or filtration steps can be incorporated into the original protocol to separate unbound antibody and marker DNA from sample cells. Because of the extremely high sensitivity of immuno-PCR, this format should allow the analysis and detection of a variety of cell surface molecules with much smaller numbers of cells than conventional antigen detection methods. It should be possible to analyze and detect such cell surface molecules even at single-cell levels.

In situ immuno-PCR has been developed for sensitive detection of antigens in tissue samples. In this method, *in situ* PCR is used to amplify a segment of the marker DNA that has been attached to antigen molecules present in tissue sections. Amplified PCR products are detected by *in situ* hybridization using a probe that is complementary to PCR products. This *in situ* immuno-PCR method has shown greater sensitivity over conventional immunohistochemistry for the detection of antigen in tissue samples.

3.5 Sensitivity

Primarily because of the enormous amplification capability of PCR, immuno-PCR has a sensitivity greater than any other antigen detection method, except for a comparable antibody-based proximity ligation method followed by PCR or rolling circle amplification. In addition to this extremely high sensitivity, overall sensitivity of immuno-PCR can be controlled systematically by varying several key factors. When the streptavidin-protein A chimera is used as a molecular linker, these key factors include concentrations of antibody, concentrations of streptavidin-protein A chimera containing end-biotinylated marker DNA, numbers of PCR amplification cycles, and detection methods for PCR products.

One such example is shown in Figs. 7 and 8. The use of a reduced concentration of the streptavidin-protein A chimera containing end-biotinylated marker DNA shifted the detection range to larger numbers of antigen. Thus, overall sensitivity of immuno-PCR can be controlled by varying the concentration of the streptavidin-protein A chimera bound to end-biotinylated marker DNA.

For given antigen samples and antibody preparations, optimal conditions where maximum sensitivity and signal-to-noise ratios can be obtained should be determined by appropriate calibration. The use of microtiter plates as a solid support greatly facilitates this optimization step, because many conditions can be tested simultaneously.

3.6 Detection of PCR Products

A variety of methods, commonly used in molecular biology and genetic

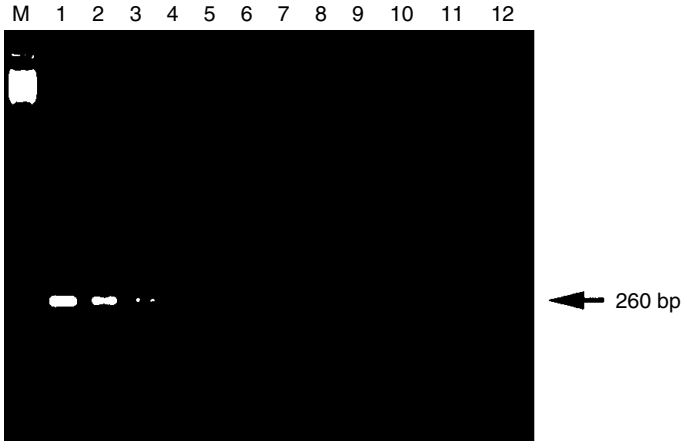

Fig. 7 Effect of a reduced concentration of the streptavidin-protein A chimera bound to end-biotinylated marker DNA on the sensitivity of immuno-PCR. The concentration of the streptavidin-protein A chimera bound to end-biotinylated marker DNA was reduced by a factor of 10, whereas all the other conditions remained the same as those in Fig. 3. Lanes 1 to 9 contain PCR amplification mixtures with immobilized antigen: Lane 1, 96 fmol (5.8×10^{10} molecules); 2, 9.6 fmol (5.8×10^{9} molecules); 3, 960 amol (5.8×10^{8} molecules); 4, 96 amol (5.8×10^{7} molecules); 5, 9.6 amol (5.8×10^{6} molecules); 6, 0.96 amol (5.8×10^{5} molecules); 7, 9.6×10^{-20} mol (5.8×10^{4} molecules); 8, 9.6×10^{-21} mol (5.8×10^{3} molecules); 9, 9.6×10^{-22} mol (5.8×10^{2} molecules). Lanes 10 to 12 are derived from control wells, where no antigen was immobilized. [Reprinted, with permission, from Sano, T., Smith, C.L., Cantor, C.R. (1992) Immuno-PCR: Very sensitive antigen detection by means of specific antibody-DNA conjugates, *Science* **258**, 120–122.]

engineering, can be used for the detection of PCR products generated by immuno-PCR. For example, conventional gel electrophoresis, in which PCR products are stained with a fluorescent dye such as ethidium bromide, can be used to analyze PCR products. This method is sufficient to perform immuno-PCR in a laboratory-scale, where relatively small numbers of samples are analyzed at a time.

A potential advantage of the use of gel electrophoresis for the detection of PCR products generated by immuno-PCR is that more than one species of PCR products can be separated and discriminated. Thus, multiple PCR products generated from single species of marker DNA with the use of more than one set of primers can be analyzed. This would provide higher accuracy in the analysis of antigen. In addition, many different antigens could be detected simultaneously, if each antigen is labeled with a different-sized marker DNA.

Analysis of a large number of samples, such as in clinical diagnostics, is facilitated by using other detection methods that are designed for this purpose and the ease of automation. For example, direct incorporation of a label, such as fluorescent dyes, haptens, and radioisotopes, into PCR products, followed by the detection

of incorporated labels, should offer simple analytical formats. Mass spectrometry of PCR products (or DNA fragments generated by primer extension of PCR products to shift to lower mass) should allow highly parallel, rapid analysis of a number of samples. It should also allow simultaneous analysis of multiple antigens, each of which is coupled to the generation of a different-sized PCR product.

3.7 Quantitation of Antigen (Epitope)

Because PCR allows the exponential amplification of a target segment, the quantitation of PCR products generated by immuno-PCR can provide an estimate of the number of antigens or epitopes in samples. The use of quantitative PCR, which has become a routine analytical method, is very useful for such effort. Mass spectrometry of PCR products (or DNA fragments generated by primer extension of PCR products) should also be quite useful. The accuracy of such estimation can be maximized by a calibration with known numbers of antigens (or epitopes). The range, where the number of antigens can be estimated by quantitation of the PCR products followed by estimation of the number of antigen, depends on the conditions used. To maximize the accuracy of estimation, several different conditions should be used. One such example can be found by comparing Figs. 3 and 4 with Figs. 7 and 8, where different concentrations of the streptavidin-protein A chimera bound to end-biotinylated marker DNA were used.

3.8 Contamination Control

One of the most important factors in avoiding background signals and false-positive signals is control of contamination, which is a problem common to all sensitive detection systems. Even though all procedures are performed very carefully, repeated use of the same marker DNA and primers may generate false-positive signals. One of the major advantages of immuno-PCR is that marker DNA is purely arbitrary. Therefore, marker DNA molecules and their primers can be changed frequently, as needed, to avoid the generation of false-positive signals caused by contamination. This characteristic offers easier control of false-positive signals than other PCR-based detection methods, in which sample-derived nucleic acids are directly amplified.

3.9 General Precautions

Immuno-PCR possesses extremely high sensitivity, derived primarily from the enormous amplification capability of PCR. Thus, any nonspecific binding of antibody and marker DNA will cause serious background problems. Extensive washing after the application of antibody and marker DNA is indispensable. Even though some fraction of specifically bound antibody and marker DNA is removed by washing, the overall sensitivity can be recovered easily by using, for example, additional amplification cycles in the PCR step.

In addition, the use of effective blocking agents is of great importance in avoiding nonspecific binding. Both protein blockers, such as nonfat dried milk and BSA, and nucleic acid blockers, such as sheared sperm DNA, are used. Because of the high specificity of PCR to target DNA defined by primers, the presence of other nucleic acid molecules does not cause the generation of background signals or false-positive signals.

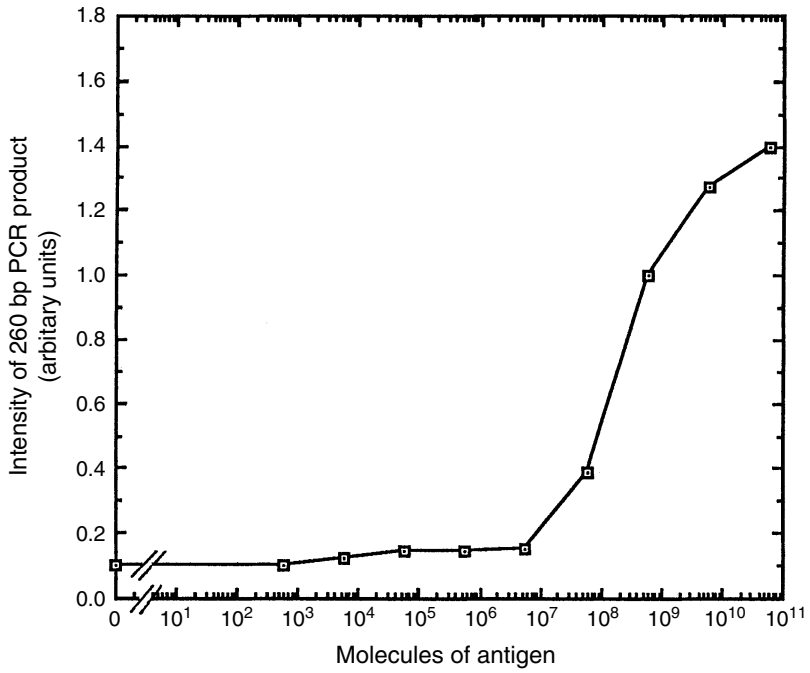

Fig. 8 Quantitation of PCR product generated by immuno-PCR shown in Fig. 7. The intensity of the 260-bp PCR fragment shown in Fig. 7 was quantitated, and plotted as a function of the number of the antigen. Note that PCR amplification was not saturated in a range from 10^7 to 10^{11} molecules of antigen, which is 10^4 to 10^5 times higher than that shown in Fig. 4. [Reprinted, with permission, from Sano, T., Smith, C.L., Cantor, C.R. (1992) Immuno-PCR: Very sensitive antigen detection by means of specific antibody-DNA conjugates, *Science* **258**, 120–122.]

4 Applications and Perspectives

Potentially, there are many areas where immuno-PCR can be applied practically and proficiently. In biological and biomedical sciences, the specific detection of biological molecules of interest is one of the most important steps in analysis. The extremely high sensitivity of immuno-PCR should allow the detection of antigens that cannot be detected by conventional antigen detection systems. Thus, the use of immuno-PCR will allow the analysis of specific antigens at microscopic scales, for example, at single-cell levels.

One of the most practical applications of immuno-PCR is in clinical diagnostics. The extremely high sensitivity of immuno-PCR will enable the specific detection of rare antigens that are present only in very small numbers. This characteristic should allow the diagnosis of diseases and infections at earlier stages of disease or infection development. Another important characteristic of immuno-PCR is its simplicity, which should allow the development of fully automated assay systems. Such automated systems are extraordinarily useful in clinical diagnostics, where large numbers of samples are analyzed repeatedly.

The distinct power and generality of immuno-PCR will allow a tremendous expansion in the applications of antibody-based detection methods, not only to biological but also to nonbiological materials. For example, the extremely high sensitivity of immuno-PCR should enable this technology to be applied to the detection of single antigen molecules, for which no method is currently available.

Keywords

Anergy
Inability to generate an immune reaction to a substance that is usually antigenic.

Indoleamine 2,3-dioxygenase
Enzyme that degrades the amino acid tryptophan. The expression of this enzyme by cells has been associated with immunosuppressive properties.

Polyamines
Naturally occurring organic amines that are critical for cellular proliferation and differentiation. Examples include putrescine, spermine, and spermadine.

Tolerance
Lack of immune response to an antigen as a result of either central (thymic) or peripheral clonal T-cell deletion or anergy.

Tumor Infiltrating Lymphocyte
Lymphocyte that infiltrates and destroys cancer cells. Maximizing the ability of these cells to kill tumor cells is the focus of much immunotherapeutic research.

Abbreviations

AICD	activation induced cell death
APC	antigen presenting cell
CEA	carcinoembryonic antigen
COX-1, COX-2	cyclooxygenase-1 and 2
CTL	cytotoxic T lymphocytes
DC	dendritic cell
DFMO	(D, L-2-(difluoromethyl) ornithine)
FAP	familial adenomatous polyposis
FasL	fas-ligand
IDO	indoleamine 2,3-dioxygenase
IFNγ	interferon gamma
LAK	lymphokine activated killer
LAP	latency associated peptide
LPS	lipopolysaccharide
MHC	major histocompatibility
MIF	macrophage migration inhibitory factor
MLR	mixed lymphocyte reaction
NK	natural killer
NO	nitric oxide
ODC	ornithine decarboxylase
PGE2	prostaglandin E2
TAP	transporter of antigen
TGFβ	transforming growth factor beta
TIL	tumor infiltrating lymphocytes
TNFα	tumor necrosis factor alpha
VEGF	vascular endothelial growth factor

Tumor cells avoid attack from the host immune system by expressing a variety of different molecules including: cytokines, prostaglandins, polyamines, enzymes, cell surface receptors, and shed antigens. Cancers that are successful in evading host antitumor defenses tend to persist, enlarge, and ultimately metastasize. Thus, an accurate identification and understanding of the various immunosuppressive factors that tumor cells employ to impair the host immune response is critical for the development of effective treatments for cancer patients. Overcoming these evasive mechanisms may be the last major obstacle to the generation of universally successful cancer therapeutics.

1 Introduction

The ability of the immune system to detect and destroy cancerous growths has been intensively debated for many years. Only recently has the consensus opinion shifted toward favoring a key role of the immune system in antitumor immunosurveillance. Several findings point to this conclusion. One is the low frequency of tumors in immunocompetent hosts and the elevated rate of malignancies in patients with immunodeficiency (even when virally induced cancers are excluded). Another argument suggesting an important role of the immune system in tumor clearance is the fact that the degree of infiltration of immune cells into tumors correlates with improved survival for patients with many different solid tumors. Mouse models have been crucial for elucidating the role of the immune system in antitumor immunity. Investigators initially concluded that murine data argued against immune system–mediated clearance of naturally developing tumors since immunocompromised mice did not develop spontaneous tumors at a higher rate than their immunocompetent counterparts. However, more recently, a strain of severely immunocompromised mice with more global immune system defects was developed. This strain displays a significantly increased number of tumors with age. Finally, as will be described in more detail below, a variety of murine models of cancer now exist which clearly demonstrate immune-mediated tumor clearance of cancers, even when tumor cells are syngeneic to the host.

It is now generally accepted, moreover, that the presence of tumor cells in an organism may not only stimulate cells of the immune system but their presence can also suppress the immune system under certain circumstances. When immunogenicity and stimulation of the host immune system predominate, destruction and clearance of cancerous cells generally occurs. Conversely, when tumor cells succeed in evading the host immune system through immunosuppressive mechanisms, they tend to survive, enlarge, and ultimately metastasize. Therefore, successful tumors acquire the ability to produce factors that subvert the host antitumor immune response. These immunosuppressive factors can repress host antitumor immune cells directly, by preventing tumor recognition and inhibiting immune cell–mediated tumor killing, but they also sometimes act indirectly by promoting host suppressor cell activity. In this article, we will discuss the effects of tumor-derived

mediators, cell surface receptors, and shed antigens on host immune cells and on tumor cells. An accurate identification and understanding of the immunosuppressive factors that hinder the host antitumor immune response will be critical for the effective treatment of cancer patients, whether by conventional means or by newly developed immunotherapeutic strategies. Overcoming the evasive mechanisms used by tumor cells to escape immune detection may be the last major obstacle to the generation of universally successful cancer therapeutics.

2 Transforming Growth Factor Beta (TGFβ)

Transforming growth factor beta (TGFβ) was originally described for its ability to induce rat kidney fibroblasts to form large colonies in soft agar in the presence of epidermal growth factor. Since that time, TGFβ has been shown to play critical roles in cell growth, differentiation, and transformation. Despite its name, however, TGFβ is generally growth inhibitory for cells. In fact, mutation of molecules in the TGFβ signaling pathway are associated with important human cancers including the inherited disease, hereditary nonpolyposis colon cancer syndrome, as well as spontaneously occurring gastric tumors, gliomas, pancreatic cancers, breast cancers, ovarian cancers, and colon cancers. Moreover, *Tgfb1* mutant mice display an increased incidence of chemically induced and spontaneous tumors while overexpression of TGFβ1 in keratinocytes makes mice resistant to chemical carcinogens.

In addition to its ability to augment cell growth, TGFβ has a variety of other effects on different cells types. TGFβ can suppress the host immune response to tumor growth and metastases. For example, in an interesting experiment, it was found that transgenic mice engineered with dominant negative, and thus nonfunctional, TGFβ receptors in either $CD4^+$ or $CD8^+$ T cells cleared melanoma and thymoma tumor cells more efficiently than wild-type mice. Moreover, TGFβ has proangiogenic and matrix inducing effects that are believed to promote tumor invasion and metastasis. Thus, in light of TGFβ's tumor-stimulating activities and despite its growth inhibitory activities, anti-TGFβ therapy is actively being pursued for the treatment of cancer.

The TGFβ superfamily consists of TGFβ1, β2, and β3, as well as an additional 40 different TGFβ-related proteins. The three mammalian isoforms (TGFβ1, 2, and 3) are synthesized as pre-pro TGFβ polypeptides that contain a signal sequence, the pro-region (latency associated peptide; LAP), and mature TGFβ (N-terminal region). The majority of TGFβ is secreted as an inactive complex associated with a second gene product known as the *latent TGFβ binding protein*. Thus, activation of the TGFβ complex is a key regulatory step for controlling the cytokine's activity. The biologic effects of TGFβ1, 2, and 3 are mediated through the same high affinity serine-threonine kinase type I and II receptors. Upon ligation of the receptors, a series of downstream signaling events occur, which include changes in proteins termed *Smads*.

2.1 Sources of TGFβ

Many cultured cells can be stimulated to secrete TGFβ, including activated (but not resting) macrophages, T cells, B cells, and natural killer (NK) cells. In addition,

numerous tumor cell types including: pancreatic, prostate, lung, colon, melanoma, and breast carcinoma cells can secrete the molecule. Elevated levels of TGFβ in serum correlate with cancer progression and reduced survival for many cancers.

While TGFβ can inhibit MHC class II expression on tumor cells, most tumor cells resist other effects of the cytokine including tumor suppressor and growth inhibitory effects. Tumor cells are rendered insensitive to the suppressive effects of TGFβ by: (1) receptor downregulation, (2) inactivating mutations within the TGFβ receptor, and/or (3) anomalies in the postreceptor TGFβ signaling pathway that includes the Smad proteins. By contrast, the cytokine has profound direct effects on immune cells expressing TGFβ receptors. Furthermore, TGFβ indirectly compromises the function of immune cells via its modification of the production of different cytokines and chemical messengers from a variety of host cells.

2.1.1 Effects of TGFβ on Monocytes/macrophages

Macrophages are important cellular coordinators of the host immune response to tumors. Macrophages serve as antigen presenting cells and also produce cytotoxic molecules, such as tumor necrosis factor alpha (TNFα) and nitric oxide (NO) that directly kill tumor cells. Macrophages promote both T- and NK-cell antitumor activities. The suppressive effects of TGFβ on monocytes/macrophages are complex and depend on the cells' origin, differentiation state, and cytokine milieu. TGFβ blocks colony stimulating factor-1-dependent proliferation of bone marrow precursor cells and hence, *affects macrophage production*. It also inhibits lipoprotein a-induced *macrophage proliferation*. Furthermore, tumor-derived TGFβ is well known for its ability to ''deactivate'' tissue macrophages that express high levels of TGFβR1 and TGFβR2. For example, TGFβ *suppresses the antitumor cytolytic activity* of bone marrow–derived macrophages preactivated with interferon gamma (IFNγ) and lipopolysaccharide (LPS) and *inhibits cytokine (TNFα) and NO production by macrophages*. Finally, *macrophages rendered dysfunctional by TGFβ have powerful inhibitory effects on the development of the host T-cell-mediated antitumor immune response*.

2.1.2 Effects of TGFβ on T lymphocytes

Multiple T-cell types, including $CD4^+$, $CD8^+$ cytotoxic T lymphocytes (CTLs), and tumor infiltrating lymphocytes (TILs) play prominent roles in the host immune response to tumors. TGFβ directly *suppresses T-lymphocyte activity*. It reduces pore-forming protein expression in human peripheral $CD8^+$ T cells and inhibits the cytolytic activity of both anti-CD3 stimulated $CD8^+$ T cells and CTLs directed against fresh tumor targets. Furthermore, TGFβ *inhibits the generation of CTLs in vitro*. Similar to its effect on macrophages, *TGFβ suppresses cytokine release by T lymphocytes*, including IFNγ, TNFα, IL-2, IL-6, IL-4 and IL-5.

The effects of TGFβ on T-cell immune responses are dependent on numerous factors, including T-cell type and activation status. Recently, in an examination of the effect of TGFβ on T cells (stimulated versus nonstimulated) exhibiting a defined phenotype ($CD4^+$ versus $CD8^+$ and Th1 versus Th2) and a defined maturational stage (naïve versus memory T cells) one group found that: (1) *TGFβ inhibits both the proliferation and differentiation of Th1 and Th2 cells*, even when TGFβ is present during primary stimulation; (2) *$CD4^+$ T cells primed in the presence of TGFβ exhibit*

reduced immune responses induced by receptor cross-linking and/or by specific antigen stimulation, which is independent of costimulatory molecule and IL-2 expression; (3) the presence of TGFβ during primary T-cell stimulation has a long-lasting or ''imprinting'' effect; (4) the immunosuppressive effects of TGFβ on T cells cannot be reversed with IL-2; and (5) *TGFβ directly suppresses memory Th1 cytokine production* by downregulating the IL-12 receptor β2 chain on T cells, while TGFβ has no effect on memory Th2 cytokine production. Therefore, tumor-derived TGFβ assist in the escape of tumors from the host cell–mediated immune response by *suppressing the host Th1 response and promoting an ineffective Th2 response.*

Similar to its many other activities, the effect of TGFβ on *T-cell proliferation* is dependent on the cell population and activation status. The addition of TGFβ to mixed lymphocyte tumor cultures results in a decrease in the number of effector $CD8^+$ CTLs generated because the cytokine inhibits their proliferation. Moreover, TGFβ inhibits the proliferation of intraepithelial $CD8^+$ lymphocytes following activation. By contrast, when naïve T cells are activated in the presence of TGFβ, they proliferate and secrete IL-2. The antiproliferative effect of TGFβ has been attributed to downregulation of the IL-2 receptor and the inhibition of IL-2 and IL-12-mediated proliferation signals. IL-2 and IL-12 are immunostimulating cytokines capable of inducing cytokine production, enhancing cytolytic activity, and promoting T-cell proliferation. There are two opposing reports describing the mechanism by which TGFβ inhibits IL-12-mediated proliferation. One shows that TGFβ blocks IL-12 induced phosphorylation and activation of the Jak-2, Tyk-2 kinases and STAT3 and 4 transcription factors in activated lymphocytes. The other states that TGFβ does not block cytokine (IL-12 and IL-2) induced JAK and STAT phosphorylation in T cells. Thus, the mechanism by which TGFβ inhibits IL-12 induced T-cell proliferation is not clear and may depend on different factors in different circumstances.

Conflicting reports of the effects of TGFβ on *T-cell apoptosis* have been described. While TGFβ has been shown in some studies to *induce T-cell apoptosis*, in other studies it has been shown to *prevent T-cell apoptosis*. These contrasting results suggest that multiple factors (microenvironment, origin of T cell, as well as the cell's differentiation and activation states) influence the T-cell apoptotic response to TGFβ. TGFβ has been reported to promote apoptosis in T cells independent of the IL-2/IL-2 receptor pathway and through the activation of caspase-like proteases in activated murine T cells. By contrast, when present during the course of T-cell activation, TGFβ *inhibits activation induced cell death* (*AICD*) *and Fas-mediated apoptosis*. AICD by T cells is one mechanism for controlling the size and the duration of the primary immune response. Further studies showed that *TGFβ prevents apoptosis in memory Th1 $CD4^+$ T cells*. The addition of TGFβ to human T cells and T-cell hybridomas significantly reduced apoptosis after activation by anti-CD3. TGFβ blockade of T-cell apoptosis was associated with decreased FasL expression. These findings suggest that TGFβ, when present at the right time, functions as a ''viability factor'' allowing the clonal expansion of effector T cells and the generation of long-lived memory T cells during the immune response. The importance of the timing of TGFβ administration for inducing T-cell apoptosis has been demonstrated *in*

vitro. When added at the initiation of T-cell mitogenesis, this cytokine does not induce T-cell apoptosis, whereas TGFβ added postactivation enhances apoptosis in T cells.

2.1.3 Effects of TGFβ on NK and Lymphokine Activated Killer (LAK) Activity

NK cells are a subset of bone marrow–derived immune cells that proliferate in response to viral and cellular invasion. Once activated, NK cells directly kill tumor cells, but do not require matching of major histocompatibility (MHC) molecules between effector and target cells. Overall, *TGFβ has an inhibitory effect on peripheral blood NK cells*. TGFβ *inhibits NK proliferation, cytokine production (IFNγ, TNFα, GM-CSF), activation, and cytotoxicity*.

NK cells represent the main precursors of lymphokine activated killer (LAK) activity. *TGFβ inhibits the induction of LAK cell activity in vitro*. Moreover, it *suppresses the production and the antitumor cytotoxic activity of LAKs*.

2.1.4 Effects of TGFβ on Dendritic Cells (DCs)

Dendritic cells (DCs) are the most powerful antigen presenting cells (APCs) of the immune system and their function is vital to the induction of primary immune responses, immunologic tolerance, and regulation of Th1/Th2 immune responses. DCs coordinate both innate and adaptive immunity-based mechanisms of tumor killing. Immature DCs express abundant intracellular levels of MHC class I and II molecules, which can present specific tumor antigens. Once matured, DCs display the MHC bound antigen on their surface together with multiple costimulatory molecules (CD40, CD50, CD54, CD58, CD80, CD83, and CD86) and potently activate resting or naïve $CD4^+$ and $CD8^+$ T cells to promote their differentiation into functional helper and effector (tumor-killing) T cells. Thus, the most important function of DCs is to sensitize the immune system to specific antigens. Because DCs are ten to one hundred times more potent APCs than B cells and monocytes/macrophages, much work has focused on using these cells to stimulate immunity against cancer.

TGFβ is immunosuppressive to DCs. The cytokine *blocks GM-CSF-induced maturation of DCs* (defined as CD86 and MHC class II expression and mixed lymphocyte reaction (MLR) stimulating activity) from mouse bone marrow progenitor cells. In addition, *TGFβ overexpressing murine bone marrow–derived DCs exhibit lower allogeneic T-cell stimulatory activity* (assessed by MLR and CTL assays) than nontransduced cells. Thus, TGFβ suppresses important DC activities required during host antitumor responses.

To function as APCs, DCs must localize, presumably from the bone marrow to the tumor site where specific antigens are present, and then antigen-loaded DCs must migrate to lymphoid tissue. Little is known about the directed migration of DCs *in vivo*. Recent studies show that *TGFβ reversibly regulates human DC chemotaxis in vitro*. TGFβ enhances the expression of the chemokine receptors CCR1, CCR3, CCR5, and CXCR4 on immature DCs and promotes their chemotaxis *in vitro*. However, the transcriptional expression of another chemokine receptor, CCR7, by mature DCs is suppressed by TGFβ. Therefore, *TGFβ might promote the migration of immature DCs, but inhibit the localization of mature DCs to the lymphoid organs during the host immune response to tumors*.

2.2 Inhibition of TGFβ: Implications for Therapy

Numerous methods for inhibiting the immunosuppressive effects of TGFβ during tumor growth have been described in experimental models. The biologic activity of mature TGFβ can be controlled by suppressing the production of TGFβ, inhibiting the activity of mature TGFβ, and/or by altering the molecule's interaction with receptors on immune cells. Examples of direct inhibition of TGFβ activity/production during tumor growth include the use of: soluble TGFβ receptors, nonsignaling TGFβ binding proteins such as decorin and alpha2 macroglobulin, neutralizing anti-TGFβ antibodies, and antisense oligonucleotides. Of note, in recent murine studies, a soluble anti-TβRII (TGFβ receptor antagonist) was found to decrease mouse mammary tumor metastasis to the lung. Also, treatment of nude mice with anti-TGFβ inhibited metastases of colonic adenocarcinomas. In humans, TGFβ immunoneutralization significantly enhanced the sensitivity of human breast carcinoma cells to cisplatin-mediated cytotoxicity *in vitro*, suggesting that TGFβ blockade during chemotherapy treatment may promote tumor cell killing. Humanized monoclonal antibodies to TGFβ are currently being studied not only for the treatment of cancers but also for systemic sclerosis, rhinitis, glaucoma, and prevention of coronary artery restenosis following angioplasty.

Although there are a few reports describing the secretion of biologically active TGFβ, the majority of TGFβ is secreted as a latent complex, as described above. This latent TGFβ complex is subsequently activated to release mature TGFβ, which consists of two identical disulfide-linked polypeptide homodimers. *Therefore, activation of the latent TGFβ complex appears to be the major regulator of TGFβ activity in vivo*. Activation of latent TGFβ occurs by both proteolytic mechanisms including: subtilisin-like proprotein convertases such as furin, plasmin, transglutaminase, and tissue and urokinase plasminogen activator, and by nonproteolytic mechanisms such as thrombospondin and mannose-6-phosphate/insulin growth factor II receptor interactions. In addition to being sources of TGFβ itself, tumor cells also express a number of proteases that can cleave and activate latent TGFβ.

Recent investigations highlight the importance of TGFβ activation by subtilisin-like convertases, such as furin. Like TGFβ, furin is ubiquitously expressed. The formation of active TGFβ by glioma cells *in vitro* can be blocked by agents that specifically inhibit the enzymatic activity of furin. *Thus, the development of agents that block the activation of the latent TGFβ complex may represent a new class of anti-immunosuppressive agents for the treatment of cancer*.

Another means of tumor therapy that is being investigated involves attempting to restore TGFβ sensitivity to tumors. Histone deacetylase inhibitors, captopril, and farnesyl transferase inhibitors have all shown promise in pharmacologic attempts to upregulate TGFβ signaling in tumor cells. Thus, these and other similar functioning drugs are being considered in the search for anticancer therapies.

Although much is known about the specific suppressive effects of TGFβ on immune cells *in vitro*, the precise role of TGFβ in host immunosuppression during tumor growth *in vivo* is not well understood. Obviously, numerous factors play a role in the host response to TGFβ during tumor growth and it has been

found that the predominant effect of this cytokine *in vivo* is not always immunosuppression. For example: (1) high expression of TGFβ is not always associated with a poor prognostic outcome in human cancer; (2) overexpression of TGFβ in experimental models does not always lead to tumor formation and immunosuppression; (3) mutations of TGFβ and the pathways through which it signals are associated with development of cancer in both humans and mice and; (4) the host response to tumors overexpressing TGFβ can vary depending on the site of tumor implantation. Despite these findings, it is generally agreed that further studies investigating the use of TGFβ inhibitors to reduce cancer-induced immunosuppression and inhibit metastases are justified on the basis of current understanding of the numerous functions of this interesting molecule.

3 Interleukin 10 (IL-10)

Human interleukin 10 (IL-10) functions as a homodimeric 17 to 20 kD glycoprotein and exhibits a high degree of homology with its nonglycosylated mouse IL-10 counterpart. Unlike TGFβ, IL-10 is synthesized and released as an active cytokine. It signals through the IL-10 receptor, a member of the IFN receptor family. The IL-10 receptor, which is expressed on numerous immune cells, is composed of two subunits: IL-10 receptor 1 (ligand binding subunit) and IL-10 receptor 2 (signaling subunit).

3.1 Sources of IL-10

IL-10 was originally identified as a product of Th2 cells in response to antigen stimulation in the presence of APCs. It is now thought that macrophages are the main physiologic source of IL-10, but the cytokine is also expressed by other immune cells including naïve and memory T cells, B cells, eosinophils, mast cells, DCs, monocytes, and tumor (melanoma)–infiltrating T cells and NK cells. Many solid tumors express IL-10 *in vitro* and *in vivo* including lung tumors, melanomas, and gliomas. In addition, leukemic tumors that originate from both the peripheral circulation and the bone marrow (both T- and B-cell tumors) express high levels of IL-10. Finally, Hodgkins as and non-Hodgkin's lymphomas can overexpress IL-10.

Elevated serum IL-10 is considered a negative prognostic indicator for numerous cancers including Hodgkin's lymphomas, metastatic melanoma, and pancreatic cancer. Circulating IL-10 often serves as a marker for (1) the progression from adenoma to carcinoma; (2) the presence of metastatic disease, and (3) the degree of malignancy of a cancer. On the basis of the significant relationships between serum IL-10 levels and the time-to-treatment failure and patients' overall survival, IL-10 is emerging as an important indicator for monitoring disease progression in cancer patients.

The general effect of IL-10 on tumor cells themselves is protective. Pretreatment of tumor target cells with IL-10 defends them from allospecific CTL lysis. Additionally, IL-10 treatment protects tumor cells by downregulating their expression of the cell surface target molecule that NK cells use for antitumor cytotoxicity. Tumor cells use IL-10 as an antiapoptotic factor and this function can protect them from the activity of cytotoxic drugs. Aside from the different protective effects that IL-10 has on tumor cells directly, perhaps its most

important function for promoting tumor growth involves its ability to suppress the host immune response.

3.1.1 Effects of IL-10 on Monocytes/macrophages

IL-10 was first described as ''cytokine synthesis inhibitory factor''. *IL-10 inhibits LPS-induced monocyte/macrophage synthesis of numerous proinflammatory cytokines including: IL-1, IL-6, IL-8, and IL-12.* In addition, *IL-10 positively regulates macrophage production of prostaglandin (another potent immunosuppressive agent), inhibits macrophage NO production, and attenuates the cytotoxic activity* of monocytes/macrophages.

IL-10 *reduces the antigen presenting capacity of certain classes of macrophages* by multiple mechanisms. *IL-10 suppresses cell surface MHC class II expression* by macrophages, in part by inhibiting the transport of peptide loaded MHC molecules to the plasma membrane. It *decreases the surface expression of CD80 and CD86,* as well as other important costimulatory molecules. Finally, IL-10 inhibits the differentiation of monocytes into dendritic cells.

By manipulating macrophage cytokine production and expression of important cell surface molecules, IL-10 reduces the APC of macrophages to specific T cells and thus, suppresses the host antitumor immune response. Interestingly, macrophages obtained from tumor-bearing hosts are more susceptible to the immunosuppressive activities of IL-10 and less sensitive to immunostimulatory factors necessary to mount an effect antitumor response.

3.1.2 Effects of IL-10 on T Lymphocytes

Beyond the indirect effects that IL-10 has on T cells through its suppressive effects on APCs (mentioned above), IL-10 also directly affects different classes of T cells by interacting with IL-10 receptors. Similar to its effect on monocytes/macrophages, IL-10 directly affects cytokine production by some T cells. For example, IL-10 *inhibits type I cytokine (IL-2, TNFα) production* by stimulated $CD4^+$ T cells. By contrast, however, IL-10 does not inhibit IFNγ secretion by $CD8^+$ T cells in response to tumor stimulation *in vivo*.

A growing literature has been developing on the role of a subset of $CD4^+$ T cells, the Th3/Tr1 or regulatory T cells, which suppress T-cell mediated immune responses and assist in the development of immunologic tolerance. IL-10 appears to be necessary for the generation of this immunomodulatory set of cells. Furthermore, IL-10 (as well as TGFβ) is a secreted cytokine that Th3 cells use to inhibit the activity of both Th1 and Th2 $CD4^+$ T cells.

The effects of IL-10 on host antitumor $CD8^+$ CTL responses are somewhat contradictory. The cytokine exhibits both immunosuppressive and immunostimulatory effects on $CD8^+$ T cells *in vitro* and *in vivo*. Under certain experimental conditions, however, the immunosuppressive effects predominate. *In vitro, IL-10 inhibits proliferative and cytotoxic T-cell responses* generated in primary MLRs. *In vivo*, IL-10 *represses CTL activity* directly by inhibiting granzyme B expression and indirectly by inhibiting the generation of functional CTLs. IL-2 or IFNγ treatment can restore the IL-10-suppressed CTL alloreactivity if administered at the time of tumor challenge, suggesting that the immunosuppressive effect of IL-10 can be blocked by Th1 type cytokines. In a mouse model examining the growth of Lewis lung tumors in mice engineered to overexpress T cell–derived IL-10, *overexpression of IL-10 significantly enhanced tumor growth.* This

enhanced growth was associated with decreased cytokine production by T cells (IL-2 and IFNγ), and suppressed cytolytic activity of $CD8^+$ T cells. Furthermore, mice produced dysfunctional splenic APCs that expressed significantly reduced cell surface levels of MHC class I, CD80, CD86, and CD11c molecules. The dysfunctional APCs could not support CTL proliferation in MLRs or promote antitumor CTL induction. DCs obtained from the IL-10 transgenic mice failed to induce antitumor $CD8^+$ T cell reactivity *in vivo* following exposure to tumor-specific peptides. Thus, this finding supports previous work which showed that IL-10 treatment of DCs reduces their allostimulatory activity for $CD8^+$ T cells and can induce alloantigen-specific anergy in $CD8^+$ T cells.

In contrast to the numerous immunosuppressive functions of IL-10 on T cells described above, under certain conditions this cytokine stimulates the host immune system and contributes to limiting the growth and metastasis of tumors. *IL-10 enhances $CD8^+$ cellular recruitment, promotes $CD8^+$ T-cell proliferation, augments the outgrowth of CTL precursor cells*, and sometimes *enhances CTL cytolytic activity*. *In vivo*, anti-IL-10 reduced the host primary CTL response in mice following immunization with B7-1^+ P815 tumor cells, *suggesting an important role of IL-10 in the host antitumor CTL response*. Furthermore, in transgenic mice engineered to overexpress IL-10 in APCs, a biphasic pattern of tumor growth was observed in which tumors grew rapidly during the first two weeks, but then completely regressed. Thus, *the effects of IL-10 on the host CTL response are complex*; T cell-derived IL-10 may function as an immunosuppressive factor, whereas APC-derived IL-10 might act as an immune stimulating factor.

Although IL-10 has direct effects on the function of various subsets of T cells, most often the inhibitory effects of IL-10 on T cells are mediated indirectly through its effect on APC functions. As mentioned previously, *IL-10 treatment of DCs induces alloantigen-specific anergy (unresponsiveness) in both $CD4^+$ and $CD8^+$ T cells* when present during antigen-specific activation. IL-10 induced $CD4^+$ T-cell anergy can be reversed by IL-2 administration or receptor cross-linking (anti-CD3/anti-CD28), as well as by immunization with mature dendritic cells. These finding may prove to be very important therapeutically in the future.

3.1.3 Effects of IL-10 on NK Cells

Overall, *IL-10 exerts an immunostimulatory effect on NK cells*. NK cells exhibit low level IL-10 receptor expression and treatment of NK cells with *IL-10 potentiates NK cytokine production and enhances NK cytotoxicity* toward tumors *in vitro*. Furthermore, although IL-10 has no effect by itself on NK proliferation, it *augments IL-2 induced NK proliferation*. These *in vitro* findings are supported *by in vivo* studies. In some experimental tumor models, IL-10 injection or IL-10 secreting tumor cells inhibit tumor metastases by an NK-dependent mechanism. Thus, it is important to recognize that unlike the majority of the host immune system that would probably be stimulated by IL-10 blockade during cancer therapy, NK-cell production and activity may be reduced with IL-10 inhibition.

3.1.4 Effects of IL-10 on DCs

DCs are central to the induction of the host antitumor immune response because of their potent antigen presenting capacity and T-cell costimulatory activity.

The majority of published studies support the immunosuppressive effects of IL-10 on DCs. *IL-10 treatment of DCs reduces their capacity to stimulate $CD4^+$ and $CD8^+$ T-cell responses and promotes T-cell anergy*. Tumor-expression of IL-10 *prevents the migration and accumulation of DCs* within tumors and can suppress GM-CSF-induced antitumor responses. *IL-10 also induces spontaneous DC apoptosis* and makes the cells more susceptible to lysis by NK cells.

The functional activities of DCs during cancer and cancer immunotherapy depend on their state of maturation. *In vitro*, exogenous *IL-10 inhibits the generation of mature monocyte-derived DCs* in response to GM-CSF and IL-4. Furthermore, DC-derived IL-10 can act in an autocrine fashion to prevent the cell's spontaneous maturation. IL-10 *promotes the differentiation of immature DCs* into macrophage-like cells with decreased MHC class II expression, suppressed phagocytic capacity, and a complete loss of the ability to express IL-12. A similar reduction of MHC class II and costimulatory molecule expression was observed in IL-10 transduced DCs when compared with control gene-modified DCs. While these IL-10 transduced DCs could not induce T-cell proliferation, they still retained the ability to augment CTL generation and NK-cell activity. Treatment of immature DCs with an anti-IL-10 antibody led to the opposite of the expected findings: it enhanced the expression of MHC, costimulatory molecules (CD80, CD83, CD86), and cytokines (TNFα, IL-12).

Thus, IL-10 exhibits complex and multifunctional activities on DCs. The immunosuppressive effects of IL-10 on DC generation, activity, migration, and survival may limit the effectiveness of the DC-based antitumor vaccines that are now being studied in clinical trials for the treatment of various forms of cancer. An improved understanding of the regulators of tumor-derived IL-10 expression and the development of appropriate anti-IL-10 strategies may improve DC trial outcomes.

3.2 Inhibition of IL-10: Implications for Therapy

Although not as well developed as anti-TGFβ strategies, several IL-10 inhibitory treatments have been considered in efforts to improve the host immune response during tumor growth *in vivo*. These include: neutralizing IL-10 antibodies, anti-IL-10 receptor antibodies, IL-10 antisense strategies, and the removal of IL-10 producing suppressor T cells. As mentioned above, aside from the expected positive effects of inhibitory therapy on relieving IL-10-induced immunosuppression, there is also reason to believe that inhibitory therapy may impinge directly on tumor cells' growth and immune-evasive tactics. For example, some melanoma cells express receptors for IL-10. When stimulated by the cytokine, growth augmentation, decreased HLA expression, and decreased adhesion molecule expression can result. Furthermore, pretreatment of melanoma cells with IL-10 completely inhibited autologous CTL-mediated lysis in one study. Thus, therapies aimed at blocking IL-10's binding to its receptor may not only make tumors more susceptible to an efficient attack by stimulating cells of the immune system, they may also directly suppress tumor-cell growth and make tumor cells more recognizable to the reinvigorated immune cells.

Antibody therapy Anti-IL-10 antibodies upregulate anticancer autoreactive T-cell responses by inhibiting the suppressive effects of the cytokine on macrophages *in vitro*. *In vivo*, anti-IL-10 promotes survival

in tumor-bearing mice, and enhances host CTL activity. It was notable in one study that antibody treatment resulted in an increased production of the Th1 cytokines IL-2, IL-12, and IFNγ by host spleen cells. Another study showed that neutralization of IL-10 with anti-IL-10 antibodies allowed an enhanced DTH response after BCG administration and augmented antitumor activity. Finally, anti-IL-10 receptor antibodies were able to abrogate the inhibition of PHA-stimulated T-cell proliferation induced by peritoneal monocytes from ovarian cancer patients. Together, these findings suggest that inhibition of IL-10 signaling in immune cells might promote the production of effective antitumor T cells.

Drug therapy Cyclophosphamide (low dose) has been used during active specific immunotherapy in patients with advanced melanoma and other metastatic cancers. The principle of using cyclophosphamide in this manner is that it may selectively reduce suppressor cell activity and decrease the production of inhibitory factors such as TGFβ, IL-10, and NO. Low-dose cyclophosphamide treatment of lymphoma-bearing rats exhibiting an impaired lymphocyte proliferative response led to a decrease in IL-10 production by T cells and, consequently, a shift in the immune response from suppression toward immunopotentiation. This state of immunostimulation was accompanied by reduced tumor growth and metastases in the cyclophosphamide-treated animals.

Removal of the source of IL-10 Gamma delta T cells accumulate in early tumor lesions and spleens of tumor-bearing animals and express both TGFβ and IL-10. Therefore, depletion of these immunosuppressive cells might lead to enhanced antitumor immune responses. In an experimental tumor model, lysis of tumor-associated gamma delta cells using a daunomycin-conjugated anti-gamma delta antibody improved host tumor-specific NK and CTL responses and resulted in tumor regression.

Complications Despite the many promising studies suggesting that therapies aimed at inhibiting IL-10 may attenuate the growth of cancers *in vivo*, not all studies report improved host antitumor immune responses following IL-10 inhibition or depletion. *In vivo, IL-10* gene transfected melanoma and mammary adenocarcinoma cells displayed significantly reduced tumorigenic and metastatic potential. Similarly, injection of IL-10 resulted in the inhibition of both B16-F10 melanoma metastases and spontaneous melanoma development in other experimental models. It is suggested that IL-10 therapy may inhibit tumor growth by downregulating the production of angiogenic molecules such as vascular endothelial growth factor (VEGF) or by augmenting NK-mediated tumor cell lysis. In several provocative studies looking at in-transit melanoma metastases in patients undergoing therapeutic vaccinations, IL-10 was found to be upregulated in responding more than in progressing lesions. Furthermore, the IL-10 level in the tumor cells was positively correlated with level of tumor regression. Taken together, these preliminary studies suggest an improved and more complete understanding of the role of IL-10 on the host immune system is needed to maximize the chances of developing a safe and effective immunomodulatory therapy.

4
Macrophage Migration Inhibitory Factor (MIF)

Macrophage migration inhibitory factor (MIF) was originally described in the 1960s as a product of activated T cells that inhibited the random migration of guinea pig macrophages. Later studies revealed the critical proinflammatory role of MIF in the host response to endotoxin. Over the past decade, a large body of work that shows multiple roles for MIF in the regulation of host inflammatory responses has been amassed. Inhibition of MIF using neutralizing antibodies significantly reduces the severity of inflammatory diseases including arthritis, peritonitis, and glomerulonephritis. In addition to its proinflammatory activities, however, our laboratory and others have identified immunosuppressive activities of MIF with regard to T-cell activation and antigen-specific T-cell responses *in vitro* and *in vivo*.

It is now known that numerous cell types constitutively express MIF, including immune cells. However, the expression of MIF is significantly higher in tumor cells than in normal cells. While enhanced tumor MIF expression often positively correlates with a more invasive phenotype and tumor recurrence after treatment, in some tumors the opposite effect is found. Recent studies suggest that in addition to its immunomodulatory effects, MIF also positively regulates cellular proliferation. Thus, MIF not only has tumor-promoting inhibitory effects on the adaptive immune system, it also promotes tumor-cell growth directly. Evidence suggesting that this is indeed the case is that transfection of antisense MIF into colon and bladder cancer cells results in decreased cellular proliferation. In addition to its pro-growth effects, the cytokine functionally inactivates the p53 tumor suppressor and inhibits p53-dependent apoptosis. Finally, MIF has pro-angiogenic properties that probably contribute to enhanced tumor growth and invasion.

The identification of the potential growth-promoting function of MIF led our group to examine the effect of MIF neutralization on tumor growth *in vivo*. We found that MIF blockade significantly inhibited tumor growth and tumor-associated angiogenesis. Similar observations demonstrating the growth promoting and pro-angiogenic functions of MIF were reported by other groups using experimental models of melanoma and colon adenocarcinoma. In agreement with the pro-tumor effects of MIF derived from anti-MIF antibody experiments, more recent work has revealed an enhanced tumor growth rate in transgenic mice overexpressing MIF.

Our laboratory examined the effect of MIF neutralization on CTL responses during tumor growth. Using the OVA-specific EG7 tumor cell model, we found that MIF immunoneutralization delays tumor growth and is associated with increased CTL activity, increased $CD8^+$ T-cell migration to the tumor, an accumulation of intratumoral $CD8^+$ T cells, and enhanced tumor-associated apoptosis. These observations are important because, as mentioned previously, cell-mediated tumor destruction relies on a rapid, extensive, and sustained infiltration of killer T cells. Furthermore, in other model systems, MIF was shown to inhibit NK-mediated lysis of endothelial cells and uveal melanoma cells. Therefore, tumor cells may secrete high levels of MIF to protect themselves from host NK- and CTL-mediated destruction. Thus, we hypothesize that tumor-derived MIF promotes host immune suppression, tumor growth, and angiogenesis

and thereby prevents tumor destruction. No cancer immunotherapeutic trials have studied MIF inhibition as of yet, but the preliminary evidence suggests that inhibition of the activity of this molecule may benefit cancer patients.

5 Prostaglandin E2 (PGE2)

Prostaglandin E2 (PGE2) is a powerful lipid mediator that influences inflammation, promotes tumor growth, and suppresses the host antitumor immune response. PGE2 belongs to a family of eicosanoids that are derived from n-3 and n-6 polyunsaturated fatty acids. Its synthesis is regulated by a series of steps following the cyclooxygenation of arachidonic acid through the action of two key regulatory enzymes: cyclooxygenase-1 and −2 (COX-1, -2). COX-1 is constitutively expressed by virtually all cells, whereas the inducible *COX-2* (''oncogene-responsive COX'') is overexpressed by many premalignant and malignant neoplasms. Higher levels of COX-2 expression by cancer cells often correlate with poorer prognosis for patients with cancer.

5.1 Sources of PGE2

PGE2 is expressed by numerous tissues and cell types, including breast fibroblasts, colonic muscle and mucosal cells, peritoneal mesothelial cells, vascular endothelial cells, and macrophages, as well as many tumors and tumor cell lines. PGE2 expression by macrophages can be induced by tumor cell factors in tumor-bearing mice.

In tumors and tumor cells, PGE2 promotes proliferation, downregulates MHC class II expression, enhances invasiveness, inhibits apoptosis, and increases vascularization. Interestingly, although IL-10, a cytokine whose production is stimulated by PGE2, is generally able to attenuate PGE2 production (in a negative feedback loop), tumor cells sometimes lose this sensitivity due to loss of expression of the IL-10 receptor. In addition to its effects of the tumor itself, PGE2 also promotes host immunosuppression during tumor progression.

5.1.1 Effects of PGE2 on Monocytes/Macrophages

Host antitumor macrophage activity inversely correlates with PGE2 expression. While host macrophages are considered to be the major source of PGE2 during tumor growth, they express PGE2 receptors and can be rendered dysfunctional by this prostaglandin. Similar to IL-10, *PGE2 inhibits Th1 cytokine synthesis (TNFα, IL-12) by macrophages while promoting ineffective Th2 cytokine production* (IL-10). The PGE2-induced shift in the host antitumor activity toward an ineffective Th2 response encourages host immunosuppression during tumor growth.

5.1.2 Effects of PGE2 on T Lymphocytes

PGE2 is immunosuppressive to various types of T cells. It has inhibitory effects on lymphocyte proliferation, cytokine production, migration, and effector activity. Very early studies showed that immunization with PGE2 significantly reduced tumor-induced immunosuppression in mice (as measured by spleen cell proliferation assays), suggesting the role of PGE2 in *suppressing T-cell proliferation*. Further studies using anti-PGE2 antibodies in experimental tumor models demonstrated the role of this lipid in *suppressing polyclonal T-cell activation and CTL generation* following MLRs

with splenic T cells. PGE2 treatment of stimulated peripheral blood lymphocytes and $CD4^+$ T cells directly *decreases IL-2 and IFNγ production and promotes IL-10 production*. $CD8^+$ T-cell effector functions are reported to be more sensitive to the suppressive effects of PGE2 than those of $CD4^+$ T cells. PGE2 inhibits T-cell migration, promotes T-cell anergy, and suppresses $CD8^+$ CTL activity *in vitro* and *in vivo*.

5.1.3 Effects of PGE2 on NK and LAK Cell Activity

Similar to its immunosuppressive effects on CTLs, *PGE2 inhibits NK and LAK cell activity*. NK activity inversely correlates with monocyte-derived PGE2 levels in patients. Moreover, removal of monocytes from the PBMCs of patients with breast cancer restores NK and LAK levels to levels comparable to those seen in healthy controls.

5.1.4 Effects of PGE2 on DCs

PGE2 inhibits DC differentiation from bone marrow precursors and also inhibits several immune stimulatory DC functions. The molecule diminishes expression of MHC class II by DCs and decreases T-cell proliferation during MLRs (using DCs as stimulatory cells). The mechanism of action of these functions includes PGE2 stimulation of IL-10 production and inhibition of IL-12 production by DCs.

5.2 Inhibition of PGE2: Implications for Therapy

Slowed tumor growth and the inhibition of metastases has been observed by *in vivo* blockade of PGE2 activity using PGE2 immunization, anti-PGE2 antibodies, and inhibition of PGE2 production using COX inhibitors. Inhibition of COX-2 (and thus PGE2 production) in the Lewis lung carcinoma model resulted in a significant decrease in IL-10 production together with a significant increase in IL-12 secretion, and restored host antitumor reactivity. Similar findings have been observed in COX knockout mice and EP2 knockout mice, a strain of mice that lacks the receptor for PGE2. In mouse models of familial adenomatous polyposis (FAP), COX-2 inhibitor treatment resulted in decreased polyp formation in the colon. Furthermore, human patients with FAP that were treated with sulindac, a nonselective COX inhibitor, displayed a significant decline in size and number of colorectal polyps. Finally, it is known that patients with colorectal and lung cancer taking NSAIDs have a significantly lower mortality rate as compared with those not taking COX inhibitors.

The precise mechanisms by which COX inhibitors slow tumor growth are not well understood, but human epidemiologic data such as the findings mentioned above suggest antineoplastic activity of COX inhibitors. COX inhibitors enhance the host CTL responses in some tumor model systems. COX inhibitors also have been associated with the inhibition of angiogenesis, tumor growth, and telomerase elongation activity in tumor cells. In light of all of this data, pharmacologic COX-2 inhibition is actively being pursued as a treatment for cancer, especially using it in conjunction with more traditional therapies, with some promising early results.

6 Indoleamine 2,3-dioxygenase (IDO)

Indoleamine 2,3-dioxygenase (IDO), a tryptophan-degrading enzyme, has potent immune suppressive capabilities. Notable recent studies detail how expression of

this enzyme prevents immune rejection of the developing fetus despite antigenic differences from the mother in which it is developing. Administration of a drug that blocks IDO resulted in abortion as a result of immune attack on the fetus in these studies. The immunosuppressive abilities of IDO have also been observed in mouse allograft rejection studies and animal models of autoimmunity.

6.1 Sources of IDO

IDO is mainly expressed by monocytes, macrophages, and DCs but can be detected in lymphocytes and NK cells as well. A large number of tested tumor cell lines and primary human tumors express the enzyme. Since tryptophan is an essential amino acid and IDO mediated-tryptophan degradation has a growth inhibitory effect on tumor cells, it is important to consider why tumor cells would retain such an enzyme. A clue comes from a study which shows that expression of IDO by tumor cells imparts on the cells the ability to inhibit T-cell proliferation. Thus, despite the growth inhibitory effect of IDO, it is now believed that expression of the enzyme confers a selective advantage on tumor cells because it allows them to avoid immune attack.

6.2 Effects of IDO on Immune Cells

In mouse models, IDO expression by tumor cells generally affords tumors protection from immune attack. In one study, a tumor that is normally rejected by tumor-specific T cells persisted and grew when it expressed IDO. The magnitude of the T-cell response to the tumor in this model was diminished when IDO was expressed by the tumor cells. In another mouse model, a drug that blocks the effects of IDO delayed tumor formation.

The postulated mechanisms to explain how IDO, an amino acid degrading enzyme, modulates the efficacy of cells of immune system are (1) causing a depletion of local stores of tryptophan and/or (2) producing toxic metabolites through metabolism of the amino acid. In fact, although tryptophan depletion is growth inhibitory to the tumor cells themselves, T cells display an even more extreme sensitivity to low tryptophan levels and growth arrest in mid-G1 phase when exposed to low tryptophan conditions. Furthermore, some IDO tryptophan metabolites are indeed directly toxic to T cells *in vitro*.

Since expression of IDO by APCs causes them to inhibit T-cell proliferation, another means by which tumors could exploit the immunosuppressive ability of IDO would be to upregulate IDO expression in local DCs or to preferentially recruit IDO-expressing DCs to tumor sites. Preliminary work shows that tumor draining lymph nodes in patients with melanoma can contain large numbers of APCs that express IDO and that the presence of IDO positive cells in sentinel lymph node cells at the time of initial diagnosis is correlated with a bad prognosis for patients. Furthermore, tumor draining lymph nodes in a mouse melanoma model contained plasmacytoid DCs that constitutively expressed IDO and could potently suppress T-cell responses. Adoptive transfer of these cells into naïve mice resulted in T-cell anergy to antigens expressed by these DCs.

6.3 Implications for Therapy

Given the preliminary promising findings in tumor models, it is not surprising

that consideration is now being given to developing anti-IDO therapies for use in cancer, especially as adjuvant therapy in combination with more traditional chemotherapeutic approaches. While the preponderance of experimental evidence to date suggests that anti-IDO therapy may be fruitful for the treatment of cancer, a degree of caution is warranted. Two studies have shown that, in contrast to its immunosuppressive effects on T cells, IDO expression is important for proper NK cell function. Inhibition of the enzyme adversely affected NK cytotoxic activity *in vitro* and *in vivo* in these studies. Furthermore, in one of these studies, pharmacologic inhibition of IDO resulted in enhanced growth of B16 melanoma cells after subcutaneous injection.

7 Cell Surface Molecules

7.1 Fas/FasL

Fas is a membrane receptor in the tumor necrosis factor receptor family that induces apoptosis after binding Fas-ligand (FasL). In fact, this cell surface molecule was first described in 1989 when an anti-Fas antibody was shown to trigger T-cell apoptosis. FasL is a 40-kDa membrane protein related to TNF that functions not only in its membrane-bound form but also in a soluble form, soluble FasL (sFasL). Soluble FasL is derived from the proteolytic cleavage of surface-expressed FasL. Fas/FasL interactions play critical roles in the deletion of autoreactive T cells, CTL-mediated cell death, and activation-induced cell death of T cells. In addition to its proapoptotic effects, FasL binding to Fas can also stimulate the production of proinflammatory cytokines.

7.1.1 Sources of FasL

Constitutive expression of FasL is found in the lung, testis, and eye. With regard to immune cells, FasL expression is found in activated B cell, T cell, macrophage, and NK cell cultures. A wide array of human tumor cell lines and human tumors *in vitro* and *in situ* produce FasL. Moreover, within tumors FasL can be cleaved from the cell surface by matrix metalloproteinases to produce soluble FasL. Elevated FasL expression in several human tumors is significantly associated with poorer prognosis, enhanced tumor metastatic rate, and increased mortality.

7.1.2 Tumor Evasion of FasL-mediated Toxicity

Many human tumors express more Fas on their surface than FasL. It might therefore be assumed that the expression of FasL by tumor cells would be detrimental for cancers as it could initiate an apoptotic cascade in neighboring tumor cells. In fact, downregulation of Fas on the tumor cell surface does correlate with poorer prognosis in many tumors. However, this is not the only mechanism by which tumor cells acquire resistance to FasL-mediated death. Several other mechanisms enable neoplastic cells to avoid cell death triggered by Fas/FasL interactions, including: (1) expression of nonfunctional Fas on the cell surface (2) overexpression of inhibitors of the Fas/FasL apoptotic pathway such as cFLIP, bcl-2, bcl-xL, and Fas-associated phosphatase-1 and (3) secretion of decoy receptors that bind and neutralize FasL.

7.1.3 Tumor-derived FasL is Functional

FasL expressed by human tumors induces apoptosis of activated Fas^+ T lymphocytes *in vitro*. Cell death can be prevented by anti-FasL antibodies, suggesting that it is

indeed initiated by Fas/FasL interaction. Moreover, augmenting expression of FasL by tumor cells results in enhanced degree of apoptosis of lymphocytes. In pathologic sections from human tumors, higher local FasL expression in particular areas correlates with elevated levels of lymphocyte apoptosis in those areas and lower numbers of viable lymphocytes. In several murine models, FasL expression on tumor cells facilitated evasion from immune system detection.

7.1.4 FasL Expression is Correlated with Improved Prognosis in Some Tumor Models

As mentioned above, FasL binding to Fas triggers not only apoptosis but also proinflammatory signals in some cells. For example, Fas/FasL interaction in DCs results in release of IL-1β and TNFα and in smooth muscle cells results in production of IL-8, IL-1α, MCP-1, and IL-6. In contrast to the previously mentioned *in vivo* data, in some tumor models the proinflammatory effects of Fas/FasL interactions dominate over the immune suppressive capabilities of tumor-expressed FasL. Tumor cells transfected with FasL were rapidly rejected after implantation in several different model systems. The rejected tumor sites were characterized by an influx of neutrophils, which were believed to mediate the tumor destruction. In a different model system, tumor cells transfected with antisense FasL displayed no improvement in clinical course as compared with controls. The precise mechanisms that govern whether the effects of Fas/FasL interaction will be predominantly pro- or anti-inflammatory are an area of active investigation. Work to date has focused on the level of FasL expression and the role of local cytokines in shaping the immune response to Fas/FasL binding. As of now, there is a debate as to whether or not FasL expressed by human tumor cells truly acts as an important immunosuppressive mediator. With further study, a means of exploiting the FasL expression displayed by many tumor cells for cancer immunotherapy may still prove to be viable.

7.2 MHC Class I: Classical and Nonclassical Receptors

7.2.1 Classical MHC Class I

CTLs recognize their targets by peptides bound to cell surface MHC class I and are crucial for the generation of antitumor immune responses. Given the requirement of MHC class I expression for recognition by CTLs, it is interesting to note that a number of tumors display decreased expression of cell surface MHC class I proteins. Indeed, loss of HLA molecule expression is associated with a poorer prognosis of some cancers. Mechanisms tumors use to decrease cell surface HLA expression include downregulation of expression of specific HLA alleles: HLA-A, HLA-B, HLA-C and also downregulation of expression of β2 microglobulin or transporter of antigen (*TAP*) genes. Dysfunction or downregulation of the gene products from the latter two can cause a complete loss of MHC class I expression. IL-10, whether tumor or immune cell-derived, is probably integrally involved in the downregulation of MHC class I on tumor cells.

In a mouse model of lung cancer, expression of MHC class I by metastatic cells depended on the immune status of the host. In immune competent hosts, lung metastases were MHC class I negative; positivity was seen only in immunocompromised mice. This suggests that in immune competent hosts, tumors downregulate MHC

class I in an attempt to "hide" from the immune system. Furthermore, the tumors derived from the immunodeficient mice were rejected when transplanted into the immunocompetent mice. Aside from this evidence, however, there is a paucity of data to directly support the hypothesis that downregulated MHC class I expression is crucial for tumor immune evasion *in vivo*. Furthermore, downregulation of MHC class I is associated with enhanced sensitivity of cells to NK cell-mediated cytotoxicity. In fact, in an animal model, loss of $\beta 2$ microglobulin, leading to a downregulation of MHC class I on tumor cells, resulted in increased susceptibility of the cells to NK-mediated cytotoxicity. Thus, in sum, while downregulation of MHC class I remains an intuitively logical candidate mechanism for tumor immune evasion, further studies will be needed to clarify this concept.

7.2.2 HLA-G

In addition to downregulating classical HLA antigens, tumor cells can also upregulate expression of the alternative HLA molecule HLA-G to avoid immune detection. HLA-G, first described with regard to its immunosuppressive effects in the context of maternofetal tolerance, encodes proteins with similarities to proteins of the MHC class I family. HLA-G proteins can be either membrane bound (the full-length isoform HLA-G1 and the truncated isoforms -G2, -G3, and -G4) or soluble (HLA-G5, -G6, or, -G7). HLA-G is expressed by a number of cancer cell types. Enhanced HLA-G expression in melanocytes correlates with malignancy better than loss of classical MHC class I expression and elevated levels of soluble HLA-G portend a poor prognosis for melanoma patients. HLA-G proteins have become an area of active interest in tumor biology as a result of their immunosuppressive effects on NK cells, T cells, and DCs.

Expression of the full-length HLA-G1 or the truncated HLA-G2, -G3, and -G4 protects tumor cells from NK- and CTL-mediated cytotoxicity. This protective effect can be blocked with an anti-HLA-G1 specific monoclonal antibody. HLA-G positive glioma cells were found to inhibit priming of CTLs and alloproliferative responses. Both cell surface and soluble HLA-G can inhibit $CD4^+$ T-cell proliferation in MLRs. Many of HLA-G1's immunosuppressive effects are a result of its direct stimulation of inhibitory receptors on the surface of immune cells including the receptors KIR2DL4, ILT2, and ILT4. Interaction of HLA-G proteins with ILT2 and ILT4 receptors on monocytes can inhibit secretion of proinflammatory cytokines and chemokines.

The soluble protein HLA-G5, generated as a product of alternative splicing of the *HLA-G* gene transcript that lacks the transmembrane and cytoplasmic domains, blocks NK and CTL-mediated cell death. Since soluble HLA-G is a nonclassical MHC class I molecule, it is not surprising that this molecule is able to bind CD8 expressed on T cells. Subsequent to an HLA-G/CD8 interaction, $CD8^+$ T cells undergo apoptosis mediated by Fas/FasL interaction. A subpopulation of NK cells that express CD8 on their cell surfaces are also susceptible to apoptosis induced by soluble HLA-G5. Still, some authors have not found an increase in $CD8^+$ T cell apoptosis when these cells are cocultured with HLA-G5-positive cells. Therefore, T-cell cytotoxicity mediated by soluble HLA-G5 may be dependent on other mitigating or promoting factors in the immune cell's environment. In addition to its apoptosis-inducing

effects, soluble HLA-G impairs the alloproliferative response and decreases the Th1/Th2 secretion profile from $CD4^+$ T cells.

HLA-G can also produce immunomodulatory effects by upregulating functional tumor cell surface HLA-E, another nonclassical HLA molecule. HLA-E, in turn, binds to an inhibitory receptor on NK and T cells to block their cytotoxic and immune stimulatory functions.

Unfortunately, as there is no rodent homolog of HLA-G, there is a lack of well-controlled data to support the hypothesis that HLA-G proteins are important for tumor-induced immune suppression *in vivo*. Nevertheless, the manipulation of MHC class I molecules on the cell surface of tumor cells, whether classical or nonclassical, is a reasonable target for anticancer immunotherapy. The finding that nonclassical molecules act by providing inhibitory signals to killer immune cells through cell surface receptors implies that interruption of those interactions with antibodies or small molecule inhibitors may lift tumor-induced immune suppression.

7.3 B7-H1

Another surface molecule tumor cells use to actively inhibit immune responses is B7-H1, a member of the B7 family of costimulatory molecules. This molecule, also known as programmed death ligand 1 (PD-L1), can induce T-cell apoptosis upon binding the programmed death-1 (PD-1) receptor on a cell's surface. PD-1 is expressed on activated $CD4^+$ T cells, $CD8^+$ T cells, B cells, and myeloid cells. B7-H1 is normally expressed only in macrophages, but it is also found in many human tumors. The tumor-expressed molecule is able to stimulate CTL cell death through induction of apoptosis. Furthermore, anti-B7-H1 antibodies can abrogate this apoptotic effect. While the importance of this cell surface molecule in human cancers *in vivo* is currently unclear, therapy aimed at interrupting the interaction between B7-H1 and PD-1 may ultimately prove to be a useful means to alleviate tumor-induced host immunosuppression.

7.4 RCAS1

RCAS1 was initially described as a cell surface molecule, found on many tumor cells, capable of inducing immunosuppression. In early studies, it was suggested that binding of RCAS1 to a putative receptor inhibited growth and induced apoptosis in a number of cells including NK, B cells, and T cells. More recently, some of these claims have been questioned. RCAS1 was shown by another group to be a predominantly Golgi-located protein that altered cell surface expression of expression of tumor-associated, normally cryptic *O*-linked glycan structures. The structures are believed to be associated with adhesion, invasion, and metastasis of cancer cells. Thus, although possibly not a cell surface receptor as originally thought, RCAS1 may still prove to be an important factor for tumor growth and survival. Notably elevated levels of tumor RCAS expression correlate with poorer prognosis in a number of human cancers. Studying the effect of RCAS1-expressing tumor cells on neighboring immune cells warrants further consideration. Disruption of these effects, whether mediated directly by RCAS1 or by cell surface glycan structures, may still prove to be a means to interfere with tumor cell survival *in vivo*.

7.5
Other Cell Surface Molecules

A number of other cell surface molecules have been associated with tumor-induced immune evasion. These include: complement receptors, CD40, and CD70. Furthermore, it has been suggested that tumors express receptors for growth factors, such as IL-2, as a means of depleting these factors from the environment so they cannot be used by local immune cells. It is extremely unlikely that all of the different cell surface molecules tumors can use to avoid immune attack have been considered at this time. The list of molecules used by tumors for this purpose will probably continue to grow for years to come.

8
Polyamines

Polyamines (putrescine, spermine, and spermadine) are naturally occurring small organic cations. Polyamines are critical for both cell proliferation and differentiation. Much of our knowledge of polyamine bioactivity stems from the use of inhibitors of polyamine biosynthesis (see below).

8.1
Sources of Polyamines

Polyamines are found in all living cells. Ingested foods are a significant exogenous source of polyamines. Polyamine levels (in the urine, serum, and red blood cells) have been positively correlated with the stage of malignancy and tumor burden for several human cancers. In addition, because dying tumor cells release high levels of polyamines, circulating polyamine levels have been proposed to serve as indicators of the success of chemotherapeutic agents.

Polyamine biosynthesis can be selectively blocked by DFMO (D, L-2-(difluoromethyl) ornithine). DFMO is an irreversible inhibitor of ornithine decarboxylase (ODC), which mediates the first step in polyamine synthesis. DFMO depletes cells of intracellular putrescine and spermidine (but not spermine) and inhibits cell proliferation without causing cell death. Since DFMO treatment is associated with weight loss and toxicity, less toxic polyamine analogs have been developed. Polyamine analogs such as N1, N8-bis(ethyl)spermidine are reported to rapidly deplete intracellular polyamines and induce cell death. Because exogenous polyamines found in food contribute to the polyamine status of an individual, blockade of endogenous and exogenous (polyamine deficient diet) polyamines is sometimes required to identify the role of polyamines on host immunosuppression during tumor growth.

Inhibitors of polyamine biosynthesis decrease tumor growth and metastases *in vivo*. Interestingly, these inhibitors prevent growth and metastases in experimental models of B16 melanoma and Lewis Lung carcinoma when tumor cells are subcutaneously implanted, but not when tumor cells are intravenously injected. Much of the antitumor activity of ODC inhibitors is attributed to their antiproliferative activity. However, polyamines also appear to play a role in the differentiation of tumor cells, protease expression, invasiveness, protection against apoptosis, malignant transformation, and tumor-associated angiogenesis. Inhibitors of polyamine biosynthesis prevent proliferation of normal and tumor cells *in vitro,* including small cell lung carcinoma, mammary tumor, and melanoma cells. Tumor cells may be more dependent on polyamines for proliferation than normal host cells due to their

increased proliferative rate. In addition to their myriad effects on tumor cells, polyamines serve as suppressors of the host immune system.

8.1.1 Effects of Polyamines on Monocytes/macrophages

Polyamine levels are associated with numerous functional activities of macrophages/monocytes that may contribute to host immunosuppression during tumor growth. Inhibitors of polyamine biosynthesis impair TNFα-mediated macrophage activation and decrease the respiratory burst of macrophages. These inhibitors also block both NO and cytokine synthesis by macrophages. A correlation between total polyamine levels and monocyte phagocytosis is found in patients with colorectal cancer. Accordingly, treatment of tumor-bearing animals with polyamine deprivation combined with low dose cyclophosphamide resulted in a synergistic inhibition of tumor growth and metastasis associated with enhanced macrophage tumoricidal activities.

8.1.2 Effects of Polyamines on T Lymphocytes

Polyamine synthesis is required for the generation of CTLs and IL-2 responsiveness in these T cells. CTL differentiation is affected by the inhibition of polyamine biosynthesis to a greater extent than CTL proliferation. *These data suggest that polyamines are immunostimulating for T cells in vitro. In vivo*, while polyamine deprivation in animals grafted with Lewis lung carcinoma tumors reversed tumor-induced immunosuppression (as measured by splenic IL-2 production and total $CD4^+$ and $CD8^+$ T-cell populations), it was not associated with any changes in host CTL activity.

8.1.3 Effects of Polyamines on NK Cells

Inhibition of polyamine biosynthesis and polyamine deprivation *in vivo* is associated with decreased tumor growth and metastases and with significantly enhanced NK cytotoxic activity. Thus, *polyamines are inhibitory for NK cells.*

8.2 Inhibition of Polyamine Biosynthesis: Implications for Therapy

As described above, inhibitors of ODC, polyamine analogs, and polyamine deficient diets have been used in animal models to suppress polyamine levels. Both ODC inhibitors and polyamine analogs have been useful in identifying the role of polyamines on tumor growth and host immunosuppression. However, polyamine inhibition as a target for cancer treatment is complicated by the ubiquitous expression of polyamines and the contribution of food sources to an individual's polyamine status. Furthermore, polyamines play a critical role in the proliferation and survival of normal cells as well as cancer cells. Future studies are required to identify mechanism(s) to target polyamine inhibitors specifically to neoplastic cells. This will improve the therapeutic index of this class of medicine.

9 Tumor Shed Immunosuppressive Molecules

Tumors can shed antigens into the environment to hinder host immune attacks. The most well-characterized immunosuppressive antigens shed from tumors are the mucins. Mucins are high molecular weight glycoproteins present on most secretory epithelial tissues. Most human

epithelial tumors overexpress aberrantly glycosylated mucins referred to as MUC-1 and MUC-2. MUC-1 has been employed as an immunotherapeutic target for cancer patients because of its ability to induce both anti-MUC-1 antibodies and CTL responses. However, soluble MUC-1 and MUC-2 have been shown to be immunosuppressive tumor antigens. Accordingly, high serum levels of MUC-1 correlate with poor survival and enhanced metastatic disease for adenocarcinoma (breast, ovarian, pancreatic, and colorectal) following active specific immunotherapy.

The release of MUC antigens from the surface of tumor cells might promote tumorigenesis and subvert the host immune system by two mechanisms. First, *release of MUC-1 by tumor cells could inhibit the effectiveness of the host anti-MUC-specific CTL response* due to the downregulation of specific tumor antigen expression. Second, the release of tumor-associated MUC-1 molecules might have *direct immunosuppressive effects on the host immune system. In vitro*, MUC1 transfection into melanoma cells decreases their susceptibility to CTL induced cytolysis. Mucins also *inhibit T-cell proliferation, suppress IL-2* and *IFNγ production* by $CD4^+$ T cells, and *negatively regulate T-cell activation* at the resting stage.

Similar to mucins, the soluble forms of annexin II and carcinoembryonic antigen (CEA), two other tumor-shed antigens, appear to function as immunosuppressive factors. Annexin is a membrane-associated glycoprotein expressed by normal and tumor cells. Annexin II expression has been correlated with higher grade tumors and poorer prognosis in cancer patients. In its soluble form, *annexin II inhibits T-cell proliferation* and *suppresses IgG and IgM secretion from peripheral blood mononuclear cells*. CEA is another example of a ''tumor antigen'' currently being evaluated for use in anticancer immunotherapeutic strategies. CEA is frequently present on colorectal tumors. Elevated circulating CEA levels correlate with poorer survival rates for patients. *The shedding of CEA* from the surface of tumor cells has been proposed to *suppress LAK cytotoxic activity* and *inhibit the activities of NK and Th1 cells*.

Finally, tumor-shed gangliosides, which are glycosphingolipids released into the tumor cell microenvironment, have immunosuppressive properties. These molecules inhibit antigen process and presentation, lymphocyte proliferation, and NK cytotoxicity *in vitro*. *In vivo*, inhibition of syngeneic antitumor immune responses has been shown with injection of highly purified gangliosides.

Thus, multiple shed tumor-associated antigens may function as immunosuppressive agents and inhibition of these factors should be considered in attempts to optimize anticancer immunotherapy.

10 Conclusion

Unfortunately, the struggle between hosts and tumors often results in defeat for the host. Despite the fact that tumors possess antigens capable of stimulating the host immune system, they succeed in escaping the innate and acquired antitumor host immune responses through multiple and complex mechanisms. Tumors evade the immune response by expressing inhibitory cell surface molecules and/or by releasing factors including: cytokines, lipids, toxic metabolites, polyamines, and tumor antigens. These molecules can suppress the host immune response and at the same time stimulate tumor growth and survival.

Much is known regarding how single tumor-derived suppressive factors impair various immune cell subtypes in isolation. However, when the effects of numerous factors on different cell types are studied in combinations in more complex systems, their immunoregulatory activities can sometimes prove to be inconsistent with expected results. Thus, the outcome of tumor rejection or growth in a host depends on the converging influence of many different host antitumor molecules and tumor-derived survival elements. These come together to influence the ultimate outcome of tumor destruction or survival in complicated and interrelated manners. Important factors that determine the tumor and host's fate include: tumor cell type, host immune competence, tumor location, cytokine milieu, timing of appearance of different factors, origin of specific immune cells, and activation status of specific immune cells.

It is almost certain that we have not yet identified all of the tumor-derived immunosuppressive factors. Thus, more extensive studies are required to improve our understanding of how tumors impair the host immune response. This information will be invaluable for the future development of improved therapeutics designed to block tumor-associated host immunosuppression in cancer patients. Ultimately, the aim of this research is to allow physicians to improve patients' antitumor immunity, whether through conventional cancer treatments, novel immunotherapeutic approaches, or more likely combinations of the two. It is humbling to recognize that despite all of the tremendous advances made to date in the field of anticancer immunotherapy, we remain at a very early stage in the practical application of this knowledge to patients.

Keywords

Cancer Therapy
Strategies to kill and eliminate transformed malignant cells using various approaches such as chemotherapy, immunotherapy, gene therapy, and others.

Immunotoxins
A form of targeted therapy approach in which a potent toxin is conjugated or genetically fused to an anitbody or other targeting moiety to specifically target the toxin to the malignant cell.

Recombinant Antibodies
Antibody molecules or their fragments generated and produced by recombinant DNA technology.

Targeted Therapy
Therapeutic strategy in which a cytotoxic drug or an effector function is delivered specifically to the malignant transformed cell by using a specific marker related to the cancerous phenotype.

Targeted cancer therapy in general and immunotherapy in particular, combines rational drug design with the progress in understanding cancer biology. This approach takes advantage of our recent knowledge of the mechanisms by which normal cells are transformed into cancer cells, thus, using the special properties of cancer cells to device novel therapeutic strategies.

Recombinant immunotoxins are excellent examples for such processes, combining the knowledge of antigen expression by cancer cells with the enormous developments in recombinant DNA technology and antibody engineering. Recombinant immunotoxins are composed of a very potent protein toxin fused to a targeting moiety such as recombinant antibody fragment or growth factor.

These molecules bind to surface antigens specific for cancer cells and kill the target cells by catalytic inhibition of protein synthesis. Recombinant immunotoxins are developed for solid tumors and hematological malignancies and have been characterized intensively for their biological activity *in vitro* on cultured tumor cell lines as well as *in vivo* in animal models of human tumor xenografts. The excellent *in vitro* and *in vivo* activities of recombinant immunotoxins have lead to their preclinical development and to the initiation of clinical trial protocols. Recent trial results have demonstrated potent clinical efficacy in patients with malignant diseases that are refractory to traditional modalities of cancer treatment; surgery, radiation therapy, and chemotherapy.

1 Introduction

The rapid progress in understanding the molecular biology of cancer cells has made a large impact on the design and development of novel therapeutic strategies. These have been developed because treatment of cancer by chemotherapy is limited by a number of factors, and usually fails in patients whose malignant cells are not sufficiently different from normal cells in their growth and metabolism. Other limiting factors are the low therapeutic index of most chemotherapeutic agents, the emergence of drug-resistant populations, tumor heterogeneity, and the presence of metastatic disease.

The concept of targeted cancer therapy is thus an important means of improving the therapeutic potential of anticancer agents and lead to the development of novel approaches such as immunotherapy. The approach of cancer immunotherapy and targeted cancer therapy combines rational drug design with the current advances in our understanding of cancer biology. This approach takes advantage of some special properties of cancer cells – many of them contain mutant or overexpressed oncogenes on their surface and these proteins are attractive antigens for targeted therapy. The first cell surface receptor to be linked to cancer was the epidermal growth factor (EGF) receptor present in lung, brain, kidney, bladder, breast, and ovarian cancer. Several other members of the EGF receptor family, that is, *erb*B2, *erb*B3, and *erb*B4 receptors, appear to be abundant on breast and ovary tumors, and *erb*B2, for example, is the target for phase I and II immunotherapy clinical trials.

Other promising candidates for targeted therapy are differentiation antigens that are expressed on the surface of mature cells, but not on the immature stem cells. The most widely studied examples of differentiation antigens currently being used for targeted therapy are expressed by hematopoietic malignancies, and include CD19, CD20, and CD22 on B-cell lymphomas and leukemias, and the interleukin (IL-)-2 receptor on T-cell leukemias. Differentiation antigens have also been found on ovarian, breast, and prostate cancer.

Another class of antigen, termed *tumor-associated antigens* (TAAs), is made up of molecules that are tightly bound to the surface of cancer cells and are associated with the transformed cancer cells. An example is the carbohydrate antigen Lewis Y (LeY) that is found in many types of solid tumors. Another class of TAAs includes cancer peptides that are presented by class I MHC molecules on the surface of tumor cells.

It should be possible to use these molecular cell surface markers as targets to eliminate the cancer cells while sparing the normal cells. For this approach to be successful, we must generate a targeting moiety that will bind very specifically to the antigen or receptor expressed on the cancer cell surface and arm this targeting moiety with an effector cytotoxic moiety. The targeting moiety can be a specific antibody directed toward the cancer antigen or a ligand for a specific overexpressed receptor. The cytotoxic arm can be a radioisotope, a cytotoxic drug, or a toxin. One strategy to achieve this is to arm antibodies that target cancer cells with powerful toxins that can originate from both plants and bacteria. The molecules generated are termed *recombinant immunotoxins*.

The goal of immunotoxin therapy is to target a very potent cytotoxic agent to cell surface molecules, which will then

internalize the cytotoxic agent, resulting in cell death. Developing this type of therapy has gained much interest in recent years. Since immunotoxins differ greatly from chemotherapy in their mode of action and toxicity profile, it is hoped that immunotoxins will have the potential to improve the systemic treatment of tumors incurable with existing modes of therapy.

As shown in Fig. 1, immunotoxins can be divided into two groups: chemical conjugates (or first-generation immunotoxins) and second-generation (or recombinant) immunotoxins. They both contain toxins that have their cell binding domains either mutated or deleted to prevent them from binding to normal cells and are either fused or chemically conjugated to a ligand or an antibody specific for cancer cells (Table 1).

This article will summarize our current understanding of the design and application of second-generation recombinant Fv–immunotoxins, which utilize recombinant antibody fragments as the targeting moiety, in the treatment of cancer, and will also discuss briefly the use of recombinant

Fig. 1 Immunotoxins for targeted cancer therapy. First-generation immunotoxins are whole mAbs to which the toxin is chemically conjugated. Second-generation immunotoxins are made by recombinant DNA technology by fusing recombinant antibody fragments to the toxin (usually a truncated or mutated form of the toxin). Three types of recombinant antibody fragments are used as the targeting moiety in recombinant immunotoxins. Fabs are composed of the light-chain and the heavy-chain Fd fragment (V_H and C_H1), connected to each other via the interchain disulfide bond between C_L and C_H1. scFv fragments are stabilized by a peptide linker, which connects the C-terminus of V_H or V_L with the N-terminus of the other domain. The V_H and V_L heterodimer in dsFv is stabilized by engineering a disulfide bond between the two domains. The biochemical and biological properties described in the lower part of the figure are depicted for B3–lysPE38 (LMB-1) (a first-generation antibody–PE chemical conjugate), B3(Fv)–PE38 (LMB-7) (second-generation recombinant scFv–immunotoxin for an scFv–immunotoxin) and B3(dsFv)–PE38 (LMB-9) (for a second-generation recombinant dsFv–immunotoxin).

antibody fragments for other modes of cancer therapy and diagnosis.

2 First- and Second-generation Immunotoxins

First-generation immunotoxins were made in the early 1970s and were composed of cancer-specific monoclonal antibodies (mAbs) to which native bacterial or plant toxins were chemically conjugated. The understanding of toxin structure–function properties and the advancement in recombinant DNA technology and antibody engineering led to important breakthroughs in the late 1980s to construct second-generation recombinant immunotoxins that are composed of recombinant antibody fragments derived from cancer-specific antibodies or phage-display libraries and truncated forms of toxins. These molecules are produced in large amounts, needed for preclinical and clinical studies, in bacteria and feature better clinical properties.

As shown in Fig. 1, first- and second-generation immunotoxins contain toxins that have their cell binding domains either mutated or deleted to prevent them from binding to normal cells, and are either chemically conjugated or fused to a ligand or an antibody specific for cancer cells.

First-generation immunotoxins, composed of whole antibodies chemically conjugated to toxins, demonstrated the feasibility of this concept. Cancer cells cultured *in vitro* could be killed under conditions in which the immunotoxin demonstrated low toxicity toward cultured normal cells. Clinical trials with these agents had some success; however, they also revealed several problems, such as nonspecific toxicity toward some normal cells, difficulties in production and, particularly for the treatment of solid tumors, poor tumor penetration due to their large size.

Second-generation immunotoxins have overcome many of these problems. Progress in the elucidation of the toxin's structure and function combined with the techniques of protein engineering facilitated the design and construction of recombinant molecules with a higher specificity for cancer cells and reduced toxicity to normal cells. At the same time, advances in recombinant DNA technology and antibody engineering enabled the generation of small antibody fragments. Thus, it was possible to decrease the size of immunotoxins significantly and to improve their tumor-penetration potential *in vivo*. The development of advanced methods of recombinant protein production enabled the large-scale production of recombinant immunotoxins of high purity and quality for clinical use in sufficient quantities to perform clinical trials.

Another strategy to target cancer cells is to construct chimeric toxins in which the engineered truncated portion of the toxin [*Pseudomonas* exotoxin (PE) or diphtheria toxin (*DT*)] gene is fused to cDNA encoding growth factors or cytokines. These include transforming growth factor (TGF)-β, insulin-like growth factor (IGF)-1, acidic and basic fibroblast growth factor (FGF), IL-2, IL-4, and IL-6. These recombinant toxins (oncotoxins) are designed to target specific tumor cells that overexpress these receptors (Fig. 1).

In the following sections, we will summarize the rationale and current knowledge on the design and application of second-generation recombinant Fv–immunotoxins that utilize recombinant antibody fragments as the targeting moiety. Recent results of clinical trials

are summarized. We will also discuss the powerful new technologies for selecting new antibodies with unique specificities and improved properties.

3 The Development of Recombinant DNA-based Immunotoxins: Design of Recombinant Immunotoxins

3.1 The Toxin Moiety

The toxins that are most commonly used to make immunotoxins are ricin, DT, and PE. These toxins belong to a group of polypeptide enzymes that catalytically inactivate protein synthesis leading to cell death. Some of these toxins have been shown to induce apoptosis.

The genes for these toxins have been cloned and expressed in *Escherichia coli*, and the crystal structures of all three proteins have been solved. This information, in combination with mutational studies, has elucidated which toxin subunits are involved in their biological activity and, most importantly, the different steps of the cytocidal process. DT, PE, ricin, and their derivatives have all been successfully used to prepare immunotoxin conjugates, but only PE- and DT-containing fusion proteins generate active recombinant immunotoxins. This is because the toxic moiety must be separated from the binding moiety after internalization. PE and DT fusion proteins generate their free toxic moieties by proteolytic processing. Ricin does not possess such a proteolytic processing site and therefore cannot be attached to the targeting moiety with a peptide bond without losing cytotoxic activity. Recently, proteolytic processing sites were introduced into ricin by recombinant DNA techniques to try to overcome this problem.

3.1.1 Plant Toxins

Ricin, or the ricin A-chain fragment, has been a commonly used toxin for conjugation to antibodies. Ricin is synthesized as single polypeptide chains and processed posttranslationally into two subunits A and B linked through a disulfide bond. Ricin is a 65-kDa glycoprotein purified from the seeds of the castor bean (*Ricinus communis*). It is composed of an A subunit, which kills cells by catalytically inactivating ribosomes. The A subunit is linked by a disulfide bond to a B subunit, which is responsible for cell binding. The B chain is a galactose-specific lectin that binds to galactose residues present on cell surface glycoproteins and glycolipids. Once the B subunit of ricin binds to the cell membrane, the protein enters the cell through coated pits and endocytic vesicles. The A and B subunits of ricin are separated by a process involving disulfide bond reduction. The A subunit of ricin translocates across an intracellular membrane to the cell cytosol, probably with the assistance of the B subunit. In the cytosol, it arrests protein synthesis by enzymatically inactivating the 28S subunit of eukaryotic ribosomes. Because native ricin is highly toxic and lacks specificity, several modified forms of ricin have been developed to prepare immunotoxins that are better tolerated by patients.

To decrease the nonspecific binding of whole ricin, the A chain alone has been coupled to antibodies. The A chain is obtained by reducing the disulfide bond that links it to the B chain. Immunotoxins composed of the ricin A chain coupled to well-internalized antibodies can be highly cytotoxic. In the absence of the B chain (the binding subunit), however, immunotoxins

made with poorly internalized antibodies are not cytotoxic.

Immunotoxins containing the ricin A chain are rapidly cleared from the circulation by the liver by the binding of mannose and fucose residues of the A chain to receptors present on the reticuloendothelial system and hepatocytes. To circumvent this problem, these carbohydrate residues were chemically modified, resulting in a deglycosylated A chain (dgA) molecule. In preclinical studies, dgA-containing immunotoxins were found to have longer half-lives in the circulation and better antitumor efficacy *in vivo*. Also, recombinant A chain produced in *E. coli* can be used in place of dgA because it is devoid of carbohydrate and is not rapidly cleared by the liver.

Another strategy to decrease the nonspecific toxicity of native ricin is to block the galactose binding sites of the B chain by cross-linking with glycopeptide or to use short cross-linkers to connect the antibody to the toxin so that the galactose binding site is sterically blocked by the antibody. Blocked ricin retains a low affinity for galactose binding sites, which enhances internalization and cytotoxicity of an antibody that binds to a poorly internalized antigen.

Other plant toxins commonly used for clinical immunotoxin construction are saporin and pokeweed antiviral protein, which are single polypeptide chains that inactivate ribosomes in a similar fashion to ricin. Because these toxins lack the binding chain (B chain), they are relatively nontoxic to cells and are used for immunotoxin production.

3.1.2 Bacterial Toxins: DT and DT Derivatives

DT is a 58-kDa protein, secreted by pathogenic *Corynebacterium diphtheria*, which contains a lysogenic β phage. DT ADP-ribosylates eukaryotic elongation factor (EF)-2 at a ''diphthamide'' residue located at His415, using NAD^+ as a cofactor. This modification arrests protein synthesis and subsequently leads to cell death. Only a few, and perhaps only one, DT molecules need to reach the cytosol in order to kill a cell. When DT is isolated from the culture medium of *C. diphtheria*, it is composed of an N-terminal 21-kDa A subunit and a C-terminal 37-kDa B subunit held together by a disulfide bond. DT is the expression product of a single gene, which when secreted into the medium is processed into two fragments by extracellular proteases. When DT is produced as a recombinant single-chain protein in *E. coli*, it is not cleaved by the bacteria, but is instead cleaved by a protease in the target cells. The A domain of DT contains its enzymatic activity. The N-terminus of the B subunit of DT (or the region between A and B in single-chain DT) mediates translocation of the A subunit into the cytoplasm. The B domain, especially its C-terminus, is responsible for the binding of DT to target cells. Deletions or mutations in this part of the molecule abolish or greatly diminish the binding and toxicity of DT. DT enters cells via coated pits and is proteolytically cleaved within the endocytic compartment, if it is not already in the two-chain form, and reduced. It also undergoes a conformational change at the acidic pH present in endosomes, which probably assists translocation of the A chain into the cytosol, perhaps via a porelike structure mediated by the B chain. Derivatives of DT that are used to make immunotoxins have the C-terminus altered by mutations or partially deleted (DAB486, DAB389, and DT388), but retain the translocation and ADP-ribosylation activity of DT. Recombinant antibody fusion proteins with such

derivatives target only cells that bind the antibody moiety of the immunotoxin.

3.1.3 Bacterial Toxins: PE and PE Derivatives

Two major research studies have enabled the use and genetic manipulation of PE for the design of immunotoxins: (1) the elucidation of the crystal structure of PE, showing the toxin to be composed of three major structural domains, and (2) the finding that these domains are different functional modules of the toxin.

PE is a single-chain 66-kDa molecule secreted by *Pseudomonas aeruginosa* that, like DT, irreversibly ADP-ribosylates the diphthamide residue of EF-2, using NAD^+ as cofactor. As a consequence, protein synthesis is inhibited and cell death ensues. PE is composed of three major domains. Different functions have been assigned to each domain by mutational analysis. The N-terminal domain Ia mediates binding to the α_2-macroglobulin receptor. Domain Ib is a small domain that lies between domains II and III, and has no known function. Domain II mediates translocation of domain III, the C-terminal ADP-ribosylating domain, into the cytosol of target cells (Fig. 2). Translocation occurs after internalization of the toxin and after a variety of other steps including a pH-induced conformational change, proteolytic cleavage at a specific site in domain II, and a reductive step that separates the amino and carboxyl fragments. Ultimately, the C-terminal portion of PE is translocated from the endoplasmic reticulum into the cytosol. Despite a similar mode of action of PE and DT, which is ADP-ribosylation, and a similar initial pathway of cell entry (internalization via coated pits and endocytic vesicles) and of processing (proteolytic cleavage and a reductive step), they share almost no sequence homology.

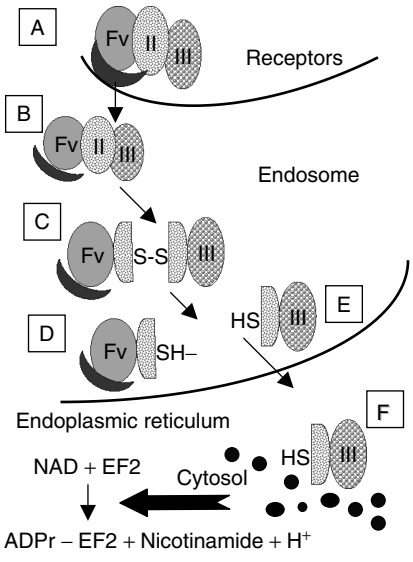

Fig. 2 The biological activity of PE A. The Fv portion of the immunotoxin targets domains II and III of PE to a cell surface receptor or other target molecule on the tumor cell (A). The immunotoxin enters the cell by internalization and is transferred into the endosome (B). Within the endosome, the molecule unfolds owing to a fall in pH. The conformational change exposes a proteolytic site, and a proteolytic cleavage occurs in the translocation domain between amino acids 279 and 280 (C). A disulfide bond is then broken, thus creating two fragments: the Fv moiety and a small part of domain II, and the rest of domain II connected to domain III (D). The C-terminal fragment containing the ADP-ribosylation domain (domain III) and most of the translocation domain (domain II) is carried into the endoplasmic reticulum (E), and translocation occurs from the endoplasmic reticulum into the cytosol (F). The enzymatically active domain ADP-ribosylates EF-2 at a diphthamide residue located at His415, using NAD^+ as a cofactor. This modification arrests protein synthesis and subsequently leads to cell death by apoptosis. In DT, the proteolytic processing occurs between residues 193 and 194. The catalytic A chain (amino acids 1–193) then translocates to the cytosol through the endosome with the help of translocation domain residues 326–347 and 358–376, which form an ion channel.

The only similarity is the spatial arrangement of key residues in their active sites that are arranged around residue Glu553 in PE and Glu145 in DT.

When the whole toxin is used to make an immunotoxin, nonspecific toxicity occurs mainly because of binding of the toxin portion to cells, mediated by the binding domain. Consequently, the goal of making improved derivatives of PE-based immunotoxins has been to inactivate or remove the binding domain. Molecules in which the binding domain has been retained but inactivated by mutations were made; however, a better alternative to inactivating the cell binding domain by mutations is to remove it from PE. The prototype molecule with this sort of deletion is PE40 (amino acids 253–613, MW 40 kDa]. Because PE40 and its derivatives described below lack the binding domain (amino acids 1–252), they have very low nonspecific toxicity, but make very active and specific immunotoxins when fused to recombinant antibodies. Currently, almost all PE-derived recombinant immunotoxins are constructed with PE38 (MW 38 kDa), a PE40 derivative that has, in addition to the deletion of domain Ia, a second deletion encompassing a portion of domain Ib (amino acids 365–379). Another useful mutation is to change the C-terminal sequence of PE from REDLK to KDEL. This improves the cytotoxicity of PE and its derivatives, presumably by increasing their delivery to the endoplasmic reticulum where translocation takes place.

3.2 The Targeting Moiety – Recombinant Antibody Fragments

The antibody moiety of the recombinant immunotoxin is responsible for specifically directing the immunotoxin to the target cell; thus, the usefulness of the immunotoxin depends on the specificity of the antibody or antibody fragment that is connected to the toxin. Consequently, for the construction of recombinant immunotoxins, the only antibodies that should be used are those that recognize antigens that are expressed on target cancer cells and are not present on normal cells, present at very low levels, or are only present on less-essential cells (Table 1). Receptors for growth factors like EGF, IL-2, IL-4, IL-6, or *erb*B2 are common targets for targeted cancer therapy because they are highly expressed on many cancer cells. Other carcinoma-related antigens include developmental antigens such as complex carbohydrates, which are often highly abundant on the surface of cancer cells.

The use of antibodies for immunotoxin production also requires that the antibody–antigen complex be internalized, because the mechanism of PE-toxin killing requires endocytosis as a first step in the entry of the toxin into the cell.

Recombinant immunotoxins contain antibody fragments as the targeting moiety. These fragments can be produced in *E. coli*, and are the result of intensive research and development in recombinant antibody technologies. Several antibody fragments have been used to construct recombinant immunotoxins (Fig. 1). One type contains Fab fragments in which the light chain and the heavy chain Fd fragment (V_H and C_H1) are connected to each other via an interchain disulfide bond between C_L and C_H1. The toxin moiety can be fused to the carboxyl end of either C_L or C_H1. Fabs can be produced in *E. coli*, either by secretion, with coexpression of light chains and Fd fragments or by expression of the chains in intracellular inclusion bodies in separate cultures; in the latter case, they are reconstituted by a

refolding reaction using a redox-shuffling buffer system. Several immunotoxins with Fab fragments have been constructed and produced in this way.

The smallest functional modules of antibodies required for antigen binding are Fv fragments. This makes them especially useful for clinical applications, not only for generating recombinant immunotoxins but also for tumor imaging, because their small size improves tumor penetration. Fv fragments are heterodimers of the variable heavy chain (V_H) and the variable light chain (V_L) domains. Unlike whole IgG or Fab, in which the heterodimers are held together and stabilized by interchain disulfide bonds, the V_H and V_L of Fvs are not covalently connected and are consequently unstable; this instability can be overcome by making recombinant Fvs that have the V_H and V_L covalently connected by a peptide linker that fuses the C-terminus of the V_L or V_H to the N-terminus of the other domain (Fig. 1). These molecules are termed *single-chain Fvs* (scFvs), and many retain the specificity and affinity of the original antibody. The cloning, construction, and composition of recombinant Fv fragments of antibodies and Fv–immunotoxins are described in Fig. 3.

Many recombinant immunotoxins have been constructed using scFvs, in which molecules, the *scFv* gene is fused to PE38 to generate a potent cytotoxic agent with targeted specificity (Figs. 1 and 3).

Until recently, the construction of scFvs was the only general method available to make stable Fvs. However, many scFvs are unstable or have reduced affinity for the antigen compared with the parent antibody or Fab fragment. This is because the linker interferes with binding or because the linker does not sufficiently stabilize the Fv structure, leading to aggregation and loss of activity. This is particularly true at physiological temperatures (37 °C). To overcome these problems, an alternative strategy has been developed that involves generating stable Fvs by connecting the V_H and V_L domains by an interchain disulfide bond engineered between structurally conserved framework residues of the Fv; these molecules are termed *disulfide-stabilized Fvs* (dsFvs). The positions at which the cysteine residues were to be placed were identified by computer-based molecular modeling; as they are located in the framework of each V_H and V_L, this location can be used as a general method to stabilize almost all Fvs without the need for any structural information. Many dsFvs have been constructed in the past three years (mainly as dsFv–immunotoxins, in which the dsFv is fused to PE38) and they show several advantages over scFvs. In addition to their increased stability (due to a decreased tendency to aggregate), they are often produced in higher yields than scFvs; in several cases, the binding affinity of the dsFv was significantly improved over that of the scFv.

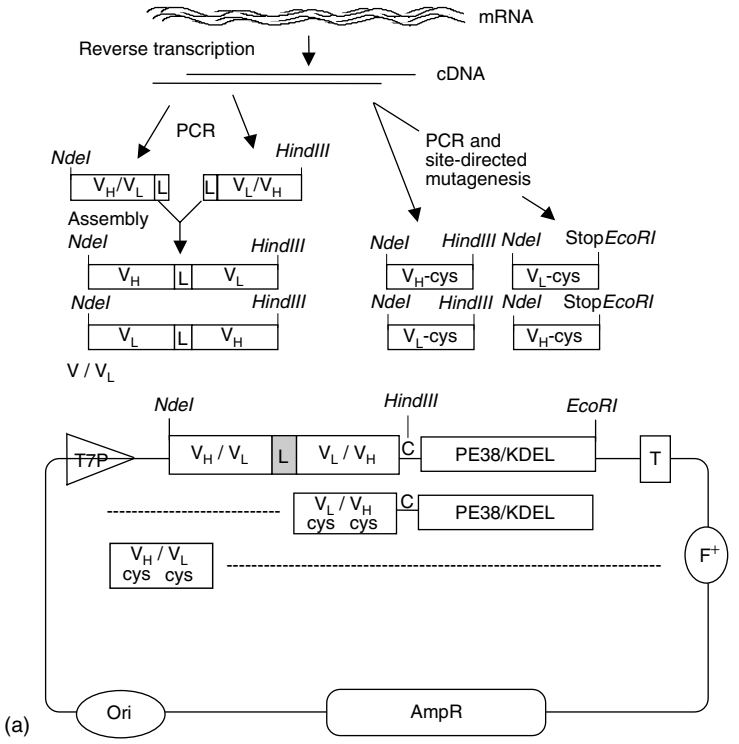
4 Construction and Production of Recombinant Immunotoxins

In the recombinant immunotoxins derived from PE, the recombinant antibody fragments are fused to the N-terminus of the truncated derivative of PE (with the cell binding domain deleted, for example, PE40 or PE38). This restores the original domain arrangement of PE, which consists of an N-terminal binding domain followed by the translocation domain and the C-terminal ADP-ribosylation domain.

Only fusions of an antigen binding domain (Fv) to the N-terminus of truncated PE are active; C-terminal fusions are

not active because the bulky antigen binding domain blocks translocation of the C-terminal fragment into the cytoplasm.

DT immunotoxins are fusions of mutated DT with antigen binding regions of a recombinant antibody. However, in this case the antigen binding domain must be fused to the C-terminus of DT. This corresponds to the inverse arrangement of the functional modules of PE and DT (see Fig. 3). DT immunotoxins are active only when the enzymatically active N-terminal domain is free to translocate into the cytosol.



The expression vectors used for DT immunotoxins are very similar to those used with PE with the exception that the DNA fragments encoding the binding moiety are ligated to the 3′-end of the DT coding region. The cloning of the antibody variable regions is performed using cloning techniques that are now well established (Fig. 3). The plasmid vector for the expression of scFv–immunotoxins or the components of dsFv–immunotoxins is a high copy–number plasmid derived from vectors made and described by Studier and Moffatt. These contain the T7 promoter, translation initiation signals, and a transcription terminator, as well as an F+ phage replication origin to generate single-stranded DNA to be used for site-directed mutagenesis.

When these plasmids are transformed into *E. coli* BL21/DE3 (which contain the *T7 RNA* polymerase gene under the control of the *lac*UV5 promoter) they generate large amounts of recombinant protein upon IPTG induction. The recombinant scFv–immunotoxin or the components of the dsFv–immunotoxin accumulate in insoluble intracellular inclusion bodies. [dsFv–immunotoxins require two cultures, one expressing the V_H and one expressing the V_L; the toxin moiety (PE38) can be fused to either the V_H or the V_L.] The inclusion bodies are then isolated, purified, solubilized, reduced, and subsequently used in a refolding reaction that is controlled for oxidation (redox shuffling). In the case of dsFv–immunotoxins, solubilized inclusion bodies of V_H and V_L

Fig. 3 Cloning, construction, and composition of scFv–and dsFv–immunotoxins. (a) Cloning and construction of recombinant scFv–and dsFv–immunotoxins. The genes encoding the V_H and V_L variable domains are cloned usually from hybridoma mRNA by reverse transcription, cDNA synthesis, and subsequent PCR amplification using degenerate primers that are complementary to the 5′ or 3′ end of the V_H and V_L genes, or by primers that are designed according to the N-terminal amino acid sequence of the mAb to be cloned and conserved sequences at the N-terminal of the heavy and light constant regions. The variable genes can be also cloned by constant domains primers and using the RACE rapid amplification of cDNA ends (method). Restriction sites for assembling the peptide linker sequence that connects the V_H and V_L domains and for cloning into the expression vector are also introduced by PCR. Construction of dsFv involves the generation of two expression plasmids that encode the two components of the dsFv V_H-Cys and V_L-Cys. The cysteines are introduced in position 44 in FR2 of V_H and position 100 of FR4 of V_L or position 105 of FR4 in V_H and position 43 of FR2 in V_L (numbering system of Kabat et al.) by site-directed mutagenesis using as a template a uracil-containing single-stranded DNA of the scFv construct from the F+ origin present in the expression plasmid and cotransfection with M13 helper phage. In addition to the cysteines, cloning sites, ATG translation initiation codons and stop codons are introduced at the 5′ and 3′ ends and of the V_H and V_L genes as shown by site-directed mutagenesis or PCR. The antibody variable genes are subcloned into an expression vector, which contains the gene for a truncated form of PE. This expression vector is controlled by the T7 promoter and upon induction of the T7 RNA polymerase, which is under the control of the *lac*UV5 promoter, in *E. coli* BL21λDE3 by IPTG, large amounts of recombinant protein are produced. (b) Composition of recombinant immunotoxins. In PE-derived recombinant Fv–immunotoxins, the Fv region of the targeting antibody is fused to the N-terminus of a truncated form of PE, which contains the translocation domain (domain II) and enzymatically active ADP-ribosylation domain (domain III]. The cell binding domain of whole PE (domain I) is replaced by the Fv targeting moiety thus preserving the relative position of the binding domain function to the other functional domains of PE. In the dsFv–immunotoxins, there are two components. In one, the V_H or V_L domains are fused to the N-terminus of the truncated PE and, in the other, the variable domain is covalently linked by the engineered disulfide bond. DT-derived immunotoxins are fused to the C-terminus due to the inverse arrangement of the functional modules of PE and DT.

(with the toxin fused to either) are mixed in a 1:1 molar ratio into the refolding solution. The formation of the interchain disulfide bond between the V_H and V_L domains is promoted by inducing oxidation using excess oxidized glutathione or by refolding at high pH. The immunotoxins are then purified from the refolding mixtures by ion-exchange and size-exclusion chromatography. Approximately 20 mg of clinical-grade active immunotoxin can be obtained from 1 L of a fermentor culture induced with IPTG.

5 Preclinical Development of Recombinant Immunotoxins

A wide variety of recombinant immunotoxins have been made and tested against cancer target cells. If found to be active and are considered to be tested in clinical trials, they undergo several years of preclinical development to determine their efficacy and toxicity in several *in vitro* and *in vivo* experimental models (Table 2).

The initial phase is the characterization of the biological activity of the immunotoxin on cultured tumor cells. These assays include measurement of cell free enzymatic activity, that is, ADP-ribosylation activity in the case of bacterial toxins, and the binding affinity of the immunotoxin to the target antigen, which can be determined on purified antigen, on cells by binding displacement assays or by surface plasmon resonance assays. Cytotoxicity assays are performed on antigen-bearing cells and measure either inhibition of protein synthesis, proliferation, colony counts or cell viability.

Cytotoxicity assays on malignant, single-cell suspensions directly obtained from patients are a very useful test, if available, since such cells contain the physiological numbers of receptor or target density, which, in many cases is lower than

Tab. 2 Functional properties *in vitro* and *in vivo* of PE-based recombinant Fv-immunotoxins.

Immunotoxin	*Specificity*	*Activity in vitro (IC_{50}) [ng mL^{-1}]*	*Binding affinity (Kd) [nM]*	*Antitumor activity in vivo (xenograft model)*
Anti-Tac(Fv)-PE38 (LMB-2)	CD25	0.15	1.4	Complete regressions/ cures (ATAC4)
B3(Fv)-PE38 (LMB-7)	Lewis Y	1.5	1300	Complete regressions/ cures (A431)
B3(dsFv)-PE38 (LMB-9)	Lewis Y	1.5	24 000	Complete regressions/ cures (A431)
e23(Fv)-PE38 (erb-38)	*erb*B2/HER2	0.3	40	Partial regressions (A431)
RFB4(dsFv)-PE38 (BL22)	CD22	10	10	Partial and some complete regressions (CA46)
SS1(Fv)-PE38	Mesothelin	0.5	11	Complete regressions/ cures (A431-K5)
MR1(Fv)-PE38	Mutant EGF-R	3.0	11	Partial regressions (glioblastoma)
55.1(Fv)-PE38	Mucin carbohydrate	0.3	80	Complete regressions (Colo205)

established cell lines. The stability of recombinant immunotoxins *in vitro* in various physiological buffers or human serum is also an important test to predict their stability *in vivo*. *In vivo* efficacy of recombinant immunotoxins is usually demonstrated in immunodeficient mice bearing xenografts of human tumor cells. The tumor xenografts can be established as subcutaneous solid tumors, orthotopic implants, or disseminated leukemia.

Initial toxicity and pharmacokinetics studies have also been performed in mice; however, many target antigens are present at some level on some normal tissues, and thus toxicology and pharmacokinetics studies should be tested in an animal that has normal cells capable of binding the target antigen. For most immunotoxins, this requires studies in monkeys to test for targeted damage to normal tissues to predict whether such damage will occur in humans.

6
Application of Recombinant Immunotoxins

6.1
Recombinant Immunotoxins against Solid Tumors

The treatment of solid tumors with immunotoxins is challenging because of their physiological nature of tight junctions between tumor cells, high interstitial pressure within tumors and heterogeneous blood supply, and also antigen expression. The greatest need for new therapies is in the treatment of metastatic epithelial cancers, and immunotoxins can be a useful addition to the standard procedures of surgery, radiation, and chemotherapy.

As already described, the use of recombinant fragments of antibodies for making recombinant immunotoxins is especially useful for the treatment of solid tumors because their small size improves tumor penetration. Over recent years, several recombinant immunotoxins that target solid tumors have been developed (Table 2); targets include breast, lung, gastric, bladder, and central nervous system cancers. They are at different stages of clinical development and some are already employed in clinical trials.

mAb B3 is an antibody that reacts with the LeY antigen present on cancers of the colon, breast, stomach, lung, and bladder. Early trials with a first-generation immunotoxin (LMB-1) in which an antibody to LeY (mAb B3) was used to make a chemical conjugate with PE38 showed significant clinical activity, with responses in colon and breast cancer. The one complete response and one partial response observed in this trial were the first major responses to immunotoxins documented for metastatic breast and colon cancer respectively.

The B3 antibody was then used to make a single-chain immunotoxin termed *B3(Fv)–PE38 or LMB-7*. LMB-7 has shown good activity against human cancer xenografts growing in mice and it is also able to cure carcinomatous meningitis in rats when given by the intrathecal route. A phase I clinical trial with LMB-7 began in 1995 and is nearing completion. During the trial, it became evident that LMB-7 lost activity when incubated at 37 °C because of aggregation, which greatly limited its ability to penetrate solid tumors.

B3(dsFv)–PE38 (LMB-9) is the dsFv version of LMB-7 with stability improved over that of LMB-7. This improved stability also allowed it to be used in a continuous-infusion mode in mice bearing human tumor xenografts; this route of administration showed an improved therapeutic

window over a bolus injection. Clinical trials with LMB-9 started in the middle of 1998. A different recombinant single-chain immunotoxin, BR96(scFv)–PE40 was derived from the anti-LeY mAb BR96 and is also currently undergoing clinical testing.

Monoclonal antibody e23 is directed at *erb*B2 (Her2/*neu*), which is highly expressed in many breast, lung, ovarian, and stomach cancers. e23(dsFv)–PE38 is a dsFv–immunotoxin composed of the Fv portion of the e23 antibody and PE38. This dsFv–immunotoxin has a significantly improved binding affinity and stability compared with its scFv analog, e23(Fv)–PE38. FRP5scFv–ETA is also a recombinant immunotoxin targeting *erb*B2. Clinical trials with e23(Fv)–PE38 were initiated in early 1998. In a phase I study on breast cancer patients, hepatotoxicity was observed in all patients. Immunohistochemistry showed the presence of *erb*B2 on hepatocytes, explaining the liver toxicity of the immunotoxin. This study demonstrated that targeting of tumors with antibodies to *erb*B2 armed with toxic agents or radioisotopes may result in unexpected organ toxicity due to the expression of the target antigen on normal cells.

Other recombinant immunotoxins that have been constructed and have antitumor activities *in vitro* and in mouse models *in vivo* include: B1(Fv)–PE38, also directed against the LeY antigen; 55.1(Fv)–PE38 and 55.1(dsFv)–PE38, which are directed at a carbohydrate mucin antigen overexpressed in colon cancers; MR1(Fv)–PE38, constructed by antibody phage-display technology and directed to a mutant EGF receptor overexpressed in liver and brain tumors; and SS(Fv)–PE38, a new recombinant immunotoxin specific for mesothelin, a differentiation antigen present on the surface of ovarian cancers, mesotheliomas, and several other types of human cancers. SS(Fv)–PE38 was constructed from an Fv fragment that was isolated by antibody-phage display from mice that underwent DNA immunization with a plasmid expressing the cloned antigen. This approach to antibody formation eliminates the need for the production of proteins for immunization.

Immunotoxins were also used to target tumors of the central nervous system. Since the transferrin receptor is expressed on tumor and normal hepatic cells but not in normal brain, several trials have targeted antitransferrin receptor immunotoxins to brain tumors. These include a conjugate of mAb 454A12 with a recombinant form of ricin-A (plant toxin), a conjugate of human transferrin with a mutant form of DT and chimeric toxin of recombinant IL-4–PE38 fusion.

6.2 Recombinant Immunotoxins against Leukemias and Lymphomas

Conventional immunotoxins, in which IgGs or Fabs are coupled to toxins, have also been used to target leukemias and lymphomas. This approach should be quite effective because many of the tumor cells are in the blood and bone marrow, where they are readily accessible to the drug. Moreover, fresh cells from patients may be easily tested for immunotoxin binding and cytotoxic activity.

Immunotoxins have also been developed for indirect treatment of malignancies by their killing of T cells that mediate graft-versus-host disease (GvHD) in the setting of allogeneic transplantation. Clinical trials using ricin-based immunoconjugates for treatment of leukemias have shown some promising results, but dose escalation has been limited by the side effects of the toxin. In addition, it is important

to eliminate not only easily accessible tumor cells but also malignant cells that are less accessible. Therefore, even for leukemias, there is a need to develop small recombinant immunotoxins that will reach cells outside the circulation. Recombinant immunotoxins targeted at leukemia and lymphoma antigens have been made with antibody fragments specific for the subunit of the IL-2 receptor (CD25) and for CD22. In addition, growth factor fusion proteins have been made that target the IL-2, IL-4, IL-6, and granulocyte macrophage colony stimulating factor (GM-CSF) receptors.

The most potent immunotoxin produced against leukemia cells is anti-Tac(Fv)–PE38 (LMB-2); this targets CD25, which is overexpressed on many T-cell leukemias. LMB-2 is very active against leukemia cell lines *in vitro* and has very good activity in animal models. It also selectively kills cells *in vitro* obtained from patients with adult T-cell leukemia without harming hematopoietic stem cells. Phase I clinical trials with LMB-2 are showing promising results. The immunotoxin was administered to 35 patients for a total of 59 treatment cycles. One hairy cell leukemia (HCL) patient achieved a complete remission, which is ongoing at 20 months. Seven partial responses were observed in cutaneous T-cell lymphoma, HCL, chronic lymphocytic leukemia, Hodgkin's disease and adult T-cell leukemia. Responding patients had a 2 to 5 log reduction of circulating malignant cells, improvement in skin lesions, and regression of lymphomatous mass and splenomegally. All four patients with HCL responded to the treatment (one with complete responses and three had 98–99.8% reductions in malignant circulating cells). A phase II trial is planned in patients with $CD25^+$ hematologic malignancies and phase I trials are planned for the prevention of GvHD in patients undergoing high-risk allotransplantation.

The conventional immunotoxin RFT5–SMPT–dgA has also been developed to target CD25 and has resulted in several responses in Hodgkin's disease, one of which lasted over two years. It is already undergoing testing for the prevention of GvHD in patients undergoing allotransplantation and has recently been shown *ex vivo* to remove alloreactive donor T cells while preserving antileukemia and antiviral T-cell responses.

A new agent, RFB4(dsFv)–PE38 (BL22), is a dsFv–immunotoxin directed at the CD22 differentiation antigen present on most B-cell leukemias. It has high cytotoxic activity on cultured tumor cells as well as in animal models and preclinical tests have been completed. This recombinant immunotoxin recently entered clinical trials in patients with leukemias. Initial phase I trials in 16 chemotherapy-resistant HCL patients resulted in 11 complete responses and two partial responses, including two partial responses in patients ineligible for LMB-2 because of $CD25^-$ HCL cells. Responses to BL22 were associated with at least a 99.5% reduction in circulating HCL cells. BL22 also induced responses in chronic lymphocytic leukemia. These recent results demonstrate that recombinant Fv–immunotoxins containing truncated PE are particularly effective in patients with chemotherapy-refractory HCL and other hematological malignancies. Other targets for the development of B-cell leukemia–specific recombinant immunotoxins include the CD19 and CD20 differentiation antigens in B-cell tumors, and CD30 in Hodgkin's lymphoma.

The B-cell lymphoma markers CD22 and CD19 were also targeted using conventional first-generation immunotoxins with

dgA – IgG–RFB4–dgA (targeting CD22) and IgG–HD37–dgA (targeting CD19). Leukemias and lymphomas were also targeted with recombinant fusions of IL-2 with truncated DT.

7 Isolation of New and Improved Antibody Fragments as Targeting Moieties: Display Technologies for the Improvement of Immunotoxin Activity

The generation of mAbs made by immunizing animals and allowing *in vivo* processes, such as immune tolerance and somatic hypermutation, to shape the antigen-combining site is a key issue for the generation of specific antibodies. The unique features required from these molecules were already described in Sect. 1 of this article. These antibodies created *in vivo* can be used for many research and diagnostic applications. Mouse mAbs might be made less immunogenic and more effective for human therapy by reformatting the binding site into chimeric or complementary-determining region (CDR)-grafted antibodies. The advances in recombinant DNA technology and antibody engineering have also led to the ability to manipulate the size of the antigen binding domain as described in this article. The two variable domains of the binding site can be cloned and arranged into a large array of possible molecular formats and sizes, and expressed in a variety of hosts, ranging from bacteria, lower eukaryotes such as yeast and fungi, to the higher eukaryotes, including mammalian cells, transgenic animals and plants. Extraordinary progress in engineering and selecting small antibody fragments for immunotherapeutic approaches has been made over the past decade, when molecular display technologies have been developed that allow us to create very large repertoires of mouse or fully human antibodies that are displayed on filamentous phage or other molecular display systems. These technologies are now revolutionizing the way in which we can build high-affinity binding sites from scratch, from any species (including humans) and use them for clinical applications such as the targeting of a drug or toxin to cancer cells as in recombinant Fv–immunotoxins.

The concept of molecular display technology relays on the physical linkage between the genotype (the antibody variable region genes) and the phenotype (antigen-binding capability) to allow simultaneous selection of the genes that encode a protein with the desired binding function. This concept can be viewed as an *in vitro* mimicking system for the natural antibody response function of the immune system. This concept was first applied by George Smith in 1985 to small peptides. The display of functional antibody repertoires on phages required several additional discoveries. First, a procedure for accessing large collections of antibody variable domains was needed; this was first described in 1989, when partially degenerate oligonucleotides priming to the 5′ and 3′ end of variable region genes and the polymerase chain reaction (PCR) were used to amplify hybridoma or large collections of variable genes. Second, as whole antibodies cannot yet be functionally expressed in bacteria, a crucial discovery was that antibody fragments (Fab or scFv) were functionally expressed in *E. coli* when they were secreted into the periplasm of the bacteria, which simulated the naturally oxidizing environment of the endoplasmic reticulum. By providing restriction sites in

the oligonucleotides used for PCR amplification, antibody libraries could thus be cloned for expression in *E. coli*. Initially, such antibody libraries were expressed from phage-λ vectors; a plaque-screening assay with labeled antigen was then used to identify antigen-specific binding sites. Such time-consuming procedures were rapidly replaced by the third seminal development: the provision of a link between the phenotype and the genotype using phages. In 1990, McCafferty et al. showed that antibody fragments could be displayed on the surface of filamentous phage particles by fusion of the antibody variable genes to one of the phage coat proteins. Multiple rounds of affinity selection could subsequently enrich antigen-specific phage antibodies, because the phage particle carries the gene encoding the displayed antibody. This was originally reported for scFv fragments, and later for Fab fragments and other antibody derivatives such as diabodies, as well as extended to various display systems. With these advances in place, it became possible to make phage antibody libraries by PCR cloning of large collections of variable region genes expressing each of the binding sites on the surface of a different phage particle and harvesting the antigen-specific binding sites by *in vitro* selection of the phage mixture on a chosen antigen. In the early 1990s, Clackson et al. showed for the first time that phage-display technology could be used to select antigen-specific antibodies from libraries made from the spleen B cells of immunized mice, thereby bypassing the requirement to immortalize the antigen-specific B cells, as in the hybridoma technology. Similarly, libraries were made from human B cells taken from animals or individuals immunized with antigen, exposed to infectious agents, with autoimmune diseases or with cancer. Thus, phage-display technology in the early 1990s had already shown the potential to replace hybridoma technology by rescuing *V* genes from immune B cells. Further advances were reported in the mid-1990s that would bypass the use of immunization and animals altogether. First, it was shown that antibodies against many different antigens could be selected from nonimmune libraries, made from the naive light-chain and heavy-chain *IgM V*-gene pools of B cells of a nonimmunized, healthy individual. Second, libraries of synthetic antibody genes, with variable genes not harvested from immune sources but consisting of germline segments artificially provided with diversity by oligonucleotide cloning, were shown to behave in a similar way to naive antibody libraries. It thus became possible to use primary antibody libraries, with huge collections of binding sites with different specificities, to select *in vitro* binding sites against most antigens, including nonimmunogenic molecules, toxic substances, and targets conserved between species.

Since these key discoveries, there have been numerous reports on applications of phage antibody libraries, ranging from basic research to drug development. In addition, many novel, related molecular display methods for antibodies have been described, including display systems on ribosomes, bacteria, and yeast cells. These technologies follow similar concepts for *in vitro* selection and improvement of binding sites. Novel selection strategies of phage-display libraries and other molecular display systems are being developed for the identification of novel antigen-binding fragments. These include selection for binding using purified or nonpurified antigen, selection for function, selection based on display capability and phage infectivity, subtractive selection procedures, and also using high-throughput selection and

screening. The use of phage-display systems will revolutionize the field of targeted drug therapy in general and the recombinant immunotoxin field in particular, because advances in this field are dependent not only on the identification of new targets on cancer cells but also on the development of new and very specific targeting moieties such as antibody fragments (scFvs). Phage-display technology now enables one to select such molecules against unique targets, especially when hybridoma technology fails to produce antibodies against an antigen or when nonimmunogenic or conserved targets between species are being used. Alternatives to phage display for making fully human antibodies are technologies developed using transgenic mice (xenomice). These transgenic mice have been engineered to lack the native murine immune repertoire and instead harbor most of the human immune system *V* genes in the germline. Injection of these ''humanized'' animals with a foreign antigen or hapten effectively evokes an immune response and a humanlike antibody is produced in the B cells. The antibody genes can be recovered from B cells either by PCR and library selection or by fusion into a monoclonal cell line by classic hybridoma technology. Several examples of recombinant Fv–immunotoxins that were constructed from scFvs isolated by phage display have already been reported and are being considered for use in clinical trials.

The phage-display approach has been used to isolate an scFv that binds with high affinity to a mutant form of the EGF receptor in which a deletion of a portion of the extracellular domain of the receptor generates a tumor-specific antigen. Another novel target for cancer therapy could be cancer-specific peptides presented on human leukocyte antigen (HLA) molecules on the surface of tumor cells. To accomplish this, it will be necessary to isolate antibodies that recognize tumor-specific peptides associated with class I MHC molecules on tumor cells. As a first step in this direction, a recombinant immunotoxin has been constructed using an antibody that was isolated by phage display and that binds specifically to peptide/MHC complexes found on virally infected cells. This recombinant immunotoxin was cytotoxic only to cells specifically expressing hemagglutinin peptide HA255–262 in complex with H-2K^k (mouse class I MHC) and was not cytotoxic to cells that express other peptides associated with H-2K^k or to cells not expressing H-2K^k. These studies indicate that, if antibodies that recognize tumor-specific peptides in the context of class I MHC molecules can be developed, they should be very useful agents for targeted cancer immunotherapy. Recently, the isolation of a human antibody directed against a peptide encoded by the melanoma-associated antigen MAGE-A1 presented by HLA-A1 molecules was reported. A large phage-Fab antibody repertoire was selected on a recombinant version of the complex. One of the selected phage antibodies shows binding to HLA-A1 complexed with the MAGE-A1 peptide, but does not show binding to HLA-A1 complexed with a peptide encoded by gene *MAGE-A3* and differing from the MAGE-A1 peptide by only three residues. Phages carrying this recombinant antibody bind to HLA-A1$^+$ cells only after *in vitro* loading with MAGE-A1 peptide. It remains now to see if such human anti-MHC/peptide complexes may prove useful for monitoring the cell surface expression of these complexes and, eventually, as a targeting reagent for the specific killing of tumor cells expressing tumor peptide/MHC complexes. The isolation of such rare antibodies against unique tumor

targets is a proof of the powerful abilities of antibody phage-display technology for the development of new generations of targeting molecules for cancer therapy and diagnosis.

Phage-display technology can be used not only to create new scFv antibodies but also to improve the properties of existing scFvs. Improvements in antibody stability, expression, and binding affinity can be achieved by using a combination of strategies including random and directed mutagenesis of CDR regions, DNA shuffling, and error-prone PCR. These mutagenesis strategies combined with the powerful selection methods available to *screen* antibody phage-display libraries can yield scFv molecules with significantly improved properties for clinical applications. For example, phage display was used to improve antibody affinity by mimicking somatic hypermutation *in vitro*. *In vivo* affinity maturation of antibodies involves mutation of hot spots in the DNA encoding the variable regions. This information was used to develop a strategy to improve antibody affinity *in vitro* using phage-display technology. The anti-mesothelin scFv, SS(scFv), was used to identify DNA sequences in the variable regions that are naturally prone to hypermutations. In a few selected hot spot regions encoding nonconserved amino acids, random mutations were introduced to make libraries with a size requirement between 10^3 and 10^4 independent clones. Panning of the hot spot libraries yielded several mutants with a 15- to 55-fold increase in affinity compared with a single clone with a 4-fold increased affinity from a library in which mutagenesis was done outside the hot spots (Table 2). This is an example of a powerful phage-display-based strategy that should be generally applicable for the rapid isolation of higher-affinity mutants of Fvs, Fabs, and other recombinant antibodies from antibody-phage libraries that are smaller in size.

In another example, random CDR mutagenesis to obtain mutants of MR1(Fv)–PE38, a single-chain recombinant immunotoxin that targets a mutant form of the EGF receptor, EGFRvIII, that is frequently overexpressed in malignant glioblastomas, was performed (Table 2). Initially, nine residues of heavy chain CDR3 were randomly mutagenized and several mutants with increased binding affinity were isolated. All mutations were in regions that correspond to a DNA hot spot. The mutant MR1Fvs with an increased affinity for EGFRvIII had an increased activity when converted to recombinant immunotoxins. A specific region of the variable region of the antibody light chain CDR3 that corresponded to a hot spot was mutagenized, and a mutant antibody with an additional increase in affinity and cytotoxic activity was isolated. These studies further show that targeting hot spots in the CDRs of Fvs is an effective approach for obtaining Fvs with increased affinity.

8 Improving The Therapeutic Window of Recombinant Immunotoxins: The Balance of Toxicity, Immunogenicity, and Efficacy

Although some of the problems, including design, large-scale production and stability, associated with the initial recombinant immunotoxins have been solved, other fundamental problems need to be addressed that are relevant to much of the immunotherapy field. Specificity, toxicity, and immunogenicity are major factors that will determine the usefulness and success of recombinant immunotoxins.

8.1 Immune Responses and Dose-limiting Toxicity

As with any cytotoxic agent, side effects such as nonspecific toxicity and immunogenicity can occur when multiple injections of immunotoxins are given. One class of side effects is due to inappropriate targeting of the immunotoxin to normal cells because of the poor specificity of the antibody. In addition, the toxin or the Fv portion of the antibody can bind nonspecifically to various tissues. For example, in mice, which usually do not contain target antigens, liver damage occurs when large amounts of immunotoxins are given. Molecular modeling combined with site-directed mutagenesis may help in the design of new versions of the toxin with decreased toxicity caused by nonspecific binding.

The development of neutralizing antibodies usually occurs after 10 days and limits the therapeutic application of immunotoxins to this 10-day period. Recent data from clinical trials indicate that patients with solid tumors develop antibodies much more readily then those with hematologic tumors. It is speculated that some hematologic tumors may be associated with less immunogenicity than others. For example, none of 14 patients with chronic lymphocytic leukemia treated with LMB-2 or BL22 have shown any evidence of antibodies.

Several approaches have been taken to reduce immunogenicity. One is to make small molecules, which appear to be less immunogenic; another is to use immunosuppressive agents such as deoxyspergualin or CTLA-4–Ig, an inhibitor of the costimulation pathways required for T-cell help and activation through the CD28/CTLA-4–CD80/CD86 complex. Another approach is to use the anti-CD20 mAb, Rituximab, which induces B-cell depletion in the majority of patients and is itself nonimmunogenic.

The dose-limiting toxicity of many immunotoxins is vascular leak syndrome (VLS). Recent studies indicate that recombinant toxins, including those containing mutated forms of PE, produce VLS in rats and that inflammation, which can be suppressed by steroids or nonsteroidal anti-inflammatory agents, mediates the VLS. VLS can also be mediated indirectly by the activation of endothelial cells and/or macrophages via cytokines such as tumor necrosis factor-α and interferon-γ. The activated cells produce nitric oxide (NO), which then can mediate oxidative damage to the endothelial cells and result in increased permeability.

Some studies demonstrate direct endothelial cell damage caused by binding the toxin to the cells. The direct damage to the cell is mediated by the enzymatic activity of the toxin, while others show an indirect damage that is mediated by binding of the targeting moiety. For example, experiments with human umbilical vein endothelial cells exposed to LMB-1 (antibody conjugate with truncated PE38) indicated that the mAb B3 rather than PE38 was binding to the LeY antigen on endothelial cells. Recent experiments using an *in vivo* model composed of human neonatal foreskin xenografts in severe combined immuno-deficient (SCID) mice identified a 3-amino acid motif present in protein toxins and in IL-2 that causes VLS without other toxin activity. Thus, VLS can be blocked in future trials with anti-inflammatory agents to block cytokine action, or by mutations or peptide inhibitors that will prevent the binding of the toxin or the targeting moiety to endothelial cells.

Toxicity can also be reduced by modifications in the scFv-targeting moiety. For example, reduction of the nonspecific animal toxicity of recombinant Fv–immunotoxin anti-Tac(Fv)–PE38 (which targets the IL-2 receptor) was achieved by introducing mutations in the framework regions of the Fv, which lower the isoelectric point (p*I*). The dose escalation with this recombinant Fv–immunotoxin (that has produced eight responses, including a durable clinically complete remission in a recently completed phase I trial of leukemias and lymphomas) was limited by liver toxicity. It was noted that the Fv of anti-Tac has a p*I* of 10.2, which brought about the hypothesis that the overall positive charge on the Fv portion of anti-Tac(Fv)–PE38 contributes to nonspecific binding to liver cells and results in dose-limiting liver toxicity. A mouse model was used to investigate the basis of this toxicity, and it was found that lowering the p*I* of the Fv of anti-Tac from 10.2 to 6.82 by selective mutation of surface residues causes a 3-fold decrease in animal toxicity and hepatic necrosis. This change in p*I* did not significantly alter the CD25 binding affinity, the cytotoxic activity toward target cells, or antitumor activity, resulting in a 3-fold improvement in the therapeutic index. If this decreased toxicity occurs in humans, it should greatly increase the clinical utility of this immunotoxin.

Another strategy to overcome the problems of nonspecific toxicity and antigenicity is by the chemical modification of the recombinant Fv–immunotoxins. An example of this was also demonstrated recently in which site-specific chemical modification with polyethylene glycol (PEGylation) of anti-Tac(Fv)–PE38 (LMB-2) improved its antitumor activity, and reduced animal toxicity and immunogenicity. PEGylation can increase plasma half-lives, stability, and therapeutic potency. To produce a PEGylated recombinant immunotoxin with improved therapeutic properties, a mutant form of anti-Tac(Fv)–PE38 (LMB-2) in which one cysteine residue was introduced into the peptide connector (ASGCGPE) between the Fv and the toxin was constructed. This mutant LMB-2 (Cys1-LMB-2), which retained full cytotoxic activity, was then site-specifically conjugated with 5 or 20 kDa of polyethylene glycol–maleimide. When compared with unmodified LMB-2, both PEGylated immunotoxins showed similar cytotoxic activities *in vitro*, but superior stability at 37 °C in mouse serum, a 5- to 8-fold increase in plasma half-lives in mice and a 3- to 4-fold increase in antitumor activity. This was accompanied by a substantial decrease in animal toxicity and immunogenicity. Site-specific PEGylation of recombinant immunotoxins may thus increase their therapeutic potency in humans.

8.2 Specificity Dictated by the Targeting Moiety

Specificity of the recombinant immunotoxin is determined by the distribution of the target antigens; several target antigens are relatively cancer specific, but are present on some normal cells in small amounts. For example, *erb*B2, although overexpressed on tumor cells, is also expressed on a limited number of normal cells. This reactivity with normal cells may cause side effects during immunotoxin therapy. It was discovered during a clinical trial that small amounts of the LeY antigen are expressed on the surface of endothelial cells and damage to these cells caused VLS. To overcome such problems, new specific targets and new reagents

against the cancer antigens that will recognize only the tumor-associated molecules must be identified and developed. The construction of large phage-display antibody libraries may result in the isolation and characterization of new reagents with improved specificity and affinity for cancer-targeted therapy.

9 Conclusions and Perspectives

Over the past decade, several second-generation recombinant immunotoxins with improved properties have been developed and are currently being evaluated in clinical trials. Several of these show clinical activity and promising results in phase I trials. The outcome of these clinical trials demonstrates that the promising preclinical results with these new agents can be translated into more substantial clinical responses, and that similar agents that target other cancer antigens merit further clinical development. These accumulating results suggest that Fv–immunotoxins merit further development as a new modality for targeted cancer treatment.

Keywords

Assisted Reproductive Technology
Refers to any intervention designed to help or improve fertility, including artificial insemination and *in vitro* fertilization.

Mitochondria
The major energy producing organelles of the oocyte; however, it is not completely clear when their metabolic role begins during early embryonic development. The sperm mitochondria are eliminated during fertilization or early embryonic development.

Oocyte
The female gamete; in most mammals, the oocyte (or egg) is arrested in metaphase of the second meiotic division before it participates in fertilization.

Spermatozoa
The male gametes; supply the paternal genome during fertilization and activate the egg to begin developing into an embryo.

Zona Pellucida
A glycoprotein envelope enclosing the oocyte; in most mammals, the zona prevents more than one spermatozoon from reaching the oocyte.

Fertilization in mammals takes place within the female reproductive tract, so information about mechanisms and molecules regulating them must come largely from studies on *in vitro* fertilization. Such studies have been most informative about fertilization mechanisms, including chemotaxis, the sperm acrosome reaction, the molecular nature of sperm–egg binding, and events occurring during and after sperm–egg plasma membrane fusion. However, many details remain to be elucidated, such as the molecular nature of sperm capacitation, the precise way in which the spermatozoon traverses the egg's zona pellucida, the identity of the sperm-derived signal that initiates egg activation, the mechanistic linkage between calcium oscillations and subsequent developmental events, and the mechanism by which paternal mitochondria are normally eliminated so that only maternal mtDNA is inherited. A major concern is whether use of novel technologies for alleviating human infertility can introduce anomalies such as paternal mtDNA inheritance, and if so, what consequences this may have for pre- or postnatal development. Until recently, it was difficult to detect small amounts of anomalous mtDNA that might be present within an embryo. However, the application of highly sensitive techniques such as RT-PCR and molecular beacon analysis can compensate for the very small numbers of oocytes that are available for analysis in mammals and so will rapidly provide further insights into the molecular mechanisms of fertilization and subsequent development.

1 Introduction

Until about 1960, most of what we knew about fertilization in animals came from studies with species such as sea urchins and frogs, for the simple reason that external fertilization allows detailed study of mechanisms and the molecules responsible for them. In contrast, very little can be deduced about mammalian fertilization as it occurs within the oviduct, except for ultrastructural observations on *in situ* fixed material. It was not until the advent of *in vitro* fertilization (IVF) technology for mammals that detailed, mechanistic studies could be undertaken. The first convincing reports of successful IVF were published in the late 1950s and the first human IVF was achieved in 1969. Even though IVF technology has been greatly improved (e.g. the ability to support sperm capacitation *in vitro*), and it is now routine in many species, there are still some inherent constraints. The relatively low number and small size of eggs that can be obtained from a single female mammal (compared with sea urchins or frogs) still impedes research progress. Moreover, mammalian IVF requires specialized and highly controlled culture conditions, such as precise gas mixtures, controlled temperatures (which vary among species), and (sometimes) specific chemical activators for spermatozoa to achieve fertilization. All these factors need to be optimized to maximize success and thus, make the most use of very limited amounts of material (eggs or embryos).

Because of the great reliance on IVF technology for advancing understanding of mammalian fertilization mechanisms, these two research areas have gone hand in hand for the past 40 years. Along the way, much has been learned about the process of fertilization, but it should be recognized that we cannot always be certain that events *in vitro* precisely represent those occurring in the natural milieu. The following sections describe some of the important findings derived from studies with mammalian gametes *in vitro* and indicate key areas where more knowledge is needed.

2 Biology of Spermatozoa

2.1 Sperm Chemotaxis

Before a spermatozoon can fertilize an egg, it has to reach the site of fertilization within the oviduct. Once it reaches there, the spermatozoon still has to make contact with the oocyte, which raises the intriguing question whether this is a random process or whether it is guided by some chemical signal released by the oocyte.

The fact that oocytes produce signals to attract spermatozoa has been well documented in marine species that reproduce by external fertilization, such as sea urchins. However, finding evidence of sperm chemotaxis in mammals as well as deciphering the nature of the signals, and the response pathways they may elicit has proven to be a much more arduous task. Early evidence suggested that follicular fluid contained substances with chemotactic properties. However, often this evidence was difficult to confirm, mainly because observations were limited to *in vitro* conditions and, more pertinently, because of the uncertainties inherent in trying to distinguish chemotaxis from random sperm accumulations that can be caused by other factors.

New support for the existence of chemotaxis in mammalian fertilization has come from recent reports of olfactory

receptors on human sperm cells. While it had been known for some time that olfactory receptor (OR) proteins can be found not only in human testicular tissues but also in the membranes of mature dog spermatozoa, the recent discovery of the odorant receptor hOR17-4 on spermatozoa has given new impetus to the idea that such receptors may be important in the ability of spermatozoa to receive chemical signals. *hOR17-4* belongs to an OR gene family that has 500 to 1000 members, many of which are expressed in the testis and several other tissues where their role is unclear. Several of the ~50 testicular ORs are made predominantly or exclusively in spermatogenic cells derived from human testicular tissue. These new ORs belong to the greater superfamily of G protein-coupled receptors, which includes the opsins and a large variety of hormone and neurotransmitter receptors. Through heterologous expression of *hOR17-4* in a human kidney cell line, it was possible to identify several agonists. One of these, bourgeonal, was not only able to induce chemotactic behavior in spermatozoa but also to produce some of the changes in intracellular Ca^{2+} usually associated with sperm modifications seen *in vitro*.

2.2 Sperm Capacitation and Hyperactivation

An important aspect of male fertility is the physiological priming of spermatozoa by a multifactorial process called *capacitation*. The culmination of this process is when spermatozoa are capable of binding to the sugar residues on the egg's extracellular envelope called the *zona pellucida* (ZP). Early attempts to use ejaculated spermatozoa for *in vitro* fertilization of oocytes met with little success. The explanation for these failures came from the work of two investigators in 1951 who discovered that spermatozoa needed to remain in the female reproductive tract for several hours before they gained the capacity to fertilize an oocyte. This process was termed *capacitation*. The modifications that occur in spermatozoa during this period are still poorly understood. Interestingly, the need for capacitation appears to be restricted to mammals where it represents the first step in a cascade of events that allows spermatozoa to rapidly undergo the necessary changes to penetrate the oocyte. As capacitation proceeds, a number of biochemical changes occur in spermatozoa (1) increased adenylyl cyclase activity and increased levels of cyclic adenosine monophosphate (cAMP), (2) protein tyrosine kinase phosphorylation of a subset of sperm components, (3) elevated intrasperm pH, (4) Ca^{2+} influx, (5) loss of sperm surface components, (6) modification/alteration of the sperm plasma membrane, and (7) changes in the surface lectin-binding patterns. Capacitation is not accompanied by visible morphological changes, but is manifested as modifications in the composition of membrane surface antigens that become accessible over the acrosome. Many intra-acrosomal contents including glycohydrolases appear on mouse and human capacitating/capacitated spermatozoa in a time-dependent manner.

In rhesus and cynomolgus monkeys, capacitation of spermatozoa has also been induced *in vitro* by exposure to the cyclic nucleotide analog dbcAMP together with caffeine. Exposure of cynomolgus spermatozoa to these reagents results in increased tyrosine phosphorylation of sperm tail proteins, which may be one of the mediators of the changes in motility associated with capacitation in this species. These motility changes, which are

characterized by a pronounced increase in the amplitude of flagellar bending, have been termed *hyperactivation* and were first reported by Yanagimachi. Other factors that have been associated with hyperactivation are an increased level of intracellular cAMP as well as a change in the level of Ca^{2+} in the flagellum and sperm head. Whether hyperactivation and capacitation are tightly coupled *in vivo* has not yet been resolved with certainty. A number of studies using various sperm treatments have shown that at least *in vitro* the two processes can be uncoupled. It is interesting to note that in humans only capacitated spermatozoa appear to be chemotactically responsive to follicular fluid, indicating that capacitation assists spermatozoa to accomplish fertilization in more than one respect. It will be interesting to determine if capacitation is a prerequisite for chemotaxis involving the olfactory receptors described by Spehr et al.

3 Fertilization

3.1 Sperm Binding to the Zona Pellucida and the Acrosome Reaction

The mammalian oocyte is surrounded by a mass of small somatic cells called *cumulus cells*, which in turn are embedded in an extracellular matrix they secrete that is rich in hyaluronic acid and contains various proteins. Spermatozoa pass through this matrix presumably with the aid of a membrane-bound hyaluronidase. The presence of one of these proteins, termed PH-20, has been confirmed in macaque and cynomolgus spermatozoa. However, Talbot showed that spermatozoa from some animals, such as frogs, which do not contain hyaluronidase, nevertheless could pass through the mammalian cumulus matrix. This makes the role of hyaluronidase in cumulus penetration somewhat inconclusive.

The zona pellucida of the oocyte contains several glycoproteins that are crucial for the ability of spermatozoa to gain access to the egg. The structure and function of these molecules have been best characterized in the mouse zona pellucida, in which there are three glycoproteins termed ZP1, ZP2, and ZP3 (alternately termed ZPA, ZPB, and ZPC). Each of these has a specific function, including binding of spermatozoa and induction of the acrosome reaction. Homologs exist in other species but there appear to be more than three zona pellucida proteins and/or their molecular weights vary over a range because of differential glycosylation. The genes encoding the zona pellucida proteins have been cloned in a variety of species including the cynomolgus monkey and baboon and these proteins have been localized histochemically on the zona pellucida in cynomolgus monkey oocytes. Binding of spermatozoa to the zona pellucida appears to be completed in two phases, comprising an initial loose attachment that is quickly followed by tighter binding. Evidence gained mostly from work in the mouse suggests that ZP3 is the protein primarily involved in the initial binding of spermatozoa and the induction of the acrosome reaction while ZP1 acts as a secondary receptor for stronger binding.

The structure of the human zona pellucida surrounding mature, preovulatory oocytes has not been routinely examined. Using antisera generated against synthetic ZP3 peptides, human metaphase II oocytes obtained after insemination *in*

vitro have been studied under a variety of conditions. Interestingly, in cases of failed fertilization with either a poor ovarian response or with morphologically defective oocytes (and in the presence of normal sperm parameters), there is a marked alteration in the zona pellucida immunoreactivity to the antisera. These findings indicated the presence of structural defects of the protein backbone of ZP3 within the zona pellucida, and suggest that this defect may also be a possible cause of fertilization failure. There is virtually no information about putative abnormalities that could operate at the level of receptor–ligand interaction during human gamete binding. Several monosaccharides located on ZP3 have been implicated as the binding epitopes including mannose, α-galactose, and β-*N*-acetylglucosamine. Much of this evidence relies on the use of synthetic oligosaccharides in competition assays *in vitro*, which allow for basic binding studies, but these may not necessarily reflect the affinities found *in vivo*.

In contrast, the ligand on the sperm membrane that mediates binding to ZP3 in primates remains to be identified. Several putative receptors have been isolated from mouse or pig spermatozoa including zonadhesin, proacrosin, and spermadhesins. The most extensively studied receptor is β1,4-galactosyltransferase. Support for its role in sperm binding has come from studies with genetically engineered mice, where overexpression has lead to increased binding to ZP3. However, it is likely that β1,4-galactosyltransferase acts in cooperation with other molecules because male mice in which β1,4-galactosyltransferase expression has been ablated remain fertile, although they exhibit altered sperm-binding characteristics and slower penetration of the zona pellucida. Further studies are necessary to elucidate the role of β1,4-galactosyltransferase in human sperm binding to the zona pellucida.

When a spermatozoon makes contact with the zona pellucida it undergoes several morphological changes that are collectively termed the *acrosome reaction*. The acrosome is a large, membrane-bound secretory vesicle, located at the anterior of spermatozoa, that contains a number of enzymes, including hyaluronidase and acrosin. Spermatozoa of many mammals (rat, bull, ram, and human) have very thin or lightly fitted acrosomes, which makes their acrosome reactions difficult to detect by light microscopy. Several methods are currently available for monitoring acrosome reactions using transmission electron microscopy, light microscopy, or by staining spermatozoa with specific fluoresceinated plant lectins. In rhesus spermatozoa, the acrosome reaction can be observed as quickly as 11 seconds after tight binding to the zona pellucida and is associated with changes in the pattern of tail movements.

During the acrosome reaction, the acrosomal membrane is modified by fusion with the overlying sperm plasma membrane resulting in the release of acrosomal enzymes. The molecular events within spermatozoa that are responsible for the acrosome reaction are not well understood. However, there is evidence that ZP3 binding activates two pathways, one leading to the opening of a channel that produces a transient influx of Ca^{2+}, the other eliciting a rise in internal pH. Both mechanisms appear necessary for the sustained release of Ca^{2+} from an intracellular Ca^{2+} pool. The acrosome reaction also causes the release and activation of acrosin, a proteolytic enzyme that is most likely one of the enzymes involved in the digestion of the zona

pellucida that facilitates the transport of spermatozoa into the perivitelline space.

3.2 Molecular Basis of Sperm–Egg Membrane Adhesion/Binding

During the last 15 years, a model for sperm–egg plasma membrane binding has been developed that suggests that this event results from the adhesion between an integrin on the egg and an integrin ligand (i.e. the disintegrin domain of a member of the ADAM family of proteins) on the spermatozoon. Initial studies showed that the sperm surface protein called *fertilin* was able to inhibit fusion with the oocyte membrane. This protein, which is composed of two subunits, is now named fertilin α (ADAM 1) and fertilin ß (ADAM 2). Sequencing of these two subunits revealed three regions of interest: (1) a metalloprotease domain that has a consensus sequence indicating enzyme activity in the fertilin α subunit but not in the fertilin ß subunit, (2) a disintegrin domain in both subunits, previously shown to be an integrin ligand in snake venom peptides, and (3) a region in the fertilin α subunit that could be modeled as an amphipathic α helix and was reminiscent of the fusion peptides of some viruses.

Both subunits of fertilin have also been identified in other mammalian species. The identification and sequencing of fertilin ß and fertilin α subunits in the mouse has led to the discovery of many other members in this new family of proteins. As new proteins have been identified, additional functions have been determined for members of this family, and it has been found that domains other than the disintegrin and metalloprotease domains may be functional. The finding that fertilin and other members of the ADAM family are present on the surface of mature spermatozoa has led to the hypothesis that spermatozoa bind via the disintegrin domain of a sperm ADAM to an egg integrin.

To further determine the involvement of specific members of the ADAM family in sperm binding (and possibly fusion), knockout mice have been generated in which the genes coding for fertilin ß, cyritestin, or both (double knockout) have been ablated. Spermatozoa from each of these mouse lines showed dramatically (90%) reduced binding to zona-free oocytes. The most plausible interpretation of these results is that each of these proteins is necessary to mediate sperm–egg plasma membrane binding.

The question of which, if any, membrane-bound integrins are required on the oocyte for sperm–egg binding (and subsequent fusion) has also been addressed using knockout mice. Recently, oocytes from mice in which expression of the α6 integrin subunit was ablated were shown to have no reduction in their capacity to bind to or fuse with sperm, suggesting that if α6 integrins do participate in sperm–egg adhesion, they are not the only molecule involved in this process.

3.3 Oocyte-sperm Fusion and Oocyte Activation

In most mammals, mature oocytes are arrested at metaphase II (MII), which is maintained by maturation promoting factor (MPF). MPF is a protein complex that consists of a kinase termed $p34^{cdc2}$ and cyclin B. Its primary function is to promote spindle assembly, chromatin condensation, and the breakdown of the nuclear envelope. The activity of MPF

appears to be regulated by the presence of cytostatic factor (CSF), which in turn requires regulation by the products of two genes, the *c-mos* proto-oncogene and *Emi1*.

After traversing the zona pellucida, the spermatozoon enters the perivitelline space and binds to the oocyte membrane, usually via the plasma membrane along the equatorial segment of the sperm head. Binding is mediated by a complex of egg membrane proteins, which probably include integrin, and bind to complementary sperm membrane molecules. Fusion with the spermatozoon results in oscillating increases in Ca^{2+} within the oocyte that in turn triggers fusion of cortical granules with the oocyte membrane and release of enzymes into the perivitelline space. These enzymes induce changes in the zona pellucida that prevent further passage of spermatozoa. Most pertinent of these changes is a modification of the structure of ZP3, which prevents further sperm binding to the zona pellucida and/or the induction of acrosome reactions in spermatozoa already bound to the zona.

The precise mechanism by which the fusion of the spermatozoon with the oocyte plasma membrane elicits the Ca^{2+} increase remains unclear, but there is strong evidence that the trigger is some factor released by the spermatozoon into the oocyte cytoplasm. This is supported by observations that rhesus monkey sperm extracts injected into oocytes can elicit Ca^{2+} oscillations similar to those observed during sperm binding. This is surprising in light of the fact that ''intracytoplasmic sperm injection'' (ICSI), in which spermatozoa are directly injected into the oocyte, not only bypasses fusion of the gametes but also alters the series of signaling events that occur in the spermatozoon prior to and during interaction with the oocyte's vestments. Recent reports suggest that ICSI and IVF induce similar initial Ca^{2+} responses, although ICSI zygotes exhibit shorter durations of Ca^{2+} oscillations and exhibit diminished degradation of the inositol 1-, 4-, 5-trisphosphate receptor-1.

Fusion of the sperm plasma membrane with the oocyte is followed by decondensation of the sperm head during which some of the proteins (protamines) used to tightly ''package'' its chromosomes are replaced by oocyte-derived histones. This is followed by formation of a pronuclear membrane and the male pronucleus. Following entry of the sperm tail into the oocyte, sperm-derived mitochondria, which were marked by ubiquitin tags during spermatogenesis, are selectively degraded by oocyte-derived factors, a phenomenon that has been observed in several species including rhesus monkeys.

How the Ca^{2+} oscillations in the oocyte are ''translated'' into the series of modifications that are observed during activation remains largely unknown. In this context, it is interesting to note that the number and amplitude of sperm-induced Ca^{2+} oscillations appear to differentially regulate the initiation, completion, and, possibly, the temporal order of most, if not all, of the events that occur during activation. One mediator of the Ca^{2+} signal appears to be Ca^{2+}/calmodulin-dependent kinase II (CaMKII). CaMKII activity undergoes transient increases in response to Ca^{2+} oscillations, while conversely inhibition of CaMKII prevents oocyte activation. CaMKII appears to be involved in the regulation of a variety of targets including cyclin degradation, secretion-promoting proteins, and control of oocyte calcium channels.

One important consequence of oocyte activation is the inactivation of MPF through degradation of its cyclin B subunit. Similarly, the mitogen-activated

protein kinase (MAP), which is involved in regulating the cell cycle and is responsible for maintenance of chromatin in its condensed state, is inactivated. Both steps are necessary for the oocyte to resume meiosis.

As a result of oocyte activation, meiosis resumes and the oocyte enters Anaphase II after which the second polar body is extruded, rendering the oocyte haploid. The chromosomes are incorporated into a female pronucleus, which is surrounded by a pronuclear membrane. Replication of male and female-derived DNA normally occurs synchronously, the pronuclear membranes disappear, and the maternal and paternal homologous chromosomes combine, a process called *syngamy*. Following syngamy, the resulting zygote initiates the first mitotic cell division.

Pronuclear migration and proper chromosomal segregation are mediated by the function of a centriole that serves initially as an organizing center for assembly of microtubules by polymerization of α-tubulin molecules. In most mammals, with the exception of mice and possibly other rodents, centrioles appear to be exclusively contributed by spermatozoa, while oocytes contain only a rudimentary similar structure. The centriole initially forms the sperm aster, which is necessary to move the female pronucleus toward its male counterpart. It is replicated during the pronuclear stage, and subsequently organizes the bipolar assembly of the mitotic spindle. In humans, defects in centrioles have been linked to reduced sperm motility and developmental arrest of embryos. The advantage of maternally derived centrioles for fertilization in rodents is unknown, but clearly this strategy is equally as effective as the exclusive reliance on sperm-derived centrioles in other species.

Understanding of the microtubule-mediated motility events that ensure normal sperm-oocyte interactions has been helped by the use of nonhuman primate gametes. Studies with rhesus monkey gametes have shown that the cytoskeletal events during fertilization by IVF and ICSI are very similar to those of human fertilization, and these manipulations of nonhuman primate gametes may help test the safety and improve the efficacy of current assisted reproductive technologies, as well as to develop new techniques. However, in the rhesus monkey, ICSI results in abnormal sperm nuclear remodeling, in part because of the persistence of vesicle-associated membrane protein (VAMP), the acrosome and the perinuclear theca on the sperm head, all of which are normally removed at, or close to, the oocyte cortex during natural and *in vitro* fertilization. Progression through the first cell cycle in ICSI oocytes cannot be completed until these structures have been removed from the developing male pronucleus, demonstrating fundamental differences between ICSI and IVF. While ICSI is of enormous therapeutic value for the treatment of male infertility, basic research using clinically relevant animal models is only now unraveling the cellular and molecular events that allow fertilization by sperm microinjection.

3.4 *In vitro* Fertilization

More than 1 million babies have been born with the help of assisted reproductive technologies since the birth of the first test tube baby more than 25 years ago. It is estimated that one in six couples are infertile. A quarter of a century later, the techniques are far from perfect and it is still important to study the basic mechanisms in animal models. While laboratory and domestic

animals have provided most of the current basic information on fertilization mechanisms and technologies, nonhuman primates are also invaluable because their reproductive physiology is very similar in most respects to that of humans. *In vitro* fertilization in nonhuman primates has been described in several species including squirrel monkeys, rhesus monkeys, cynomolgus monkeys, pigtail macaques, baboons, marmosets, chimpanzees, and lowland gorilla, although in most early experiments the rates of *in vitro* development of IVF embryos were low. Development to the morula stage in rhesus embryos generated by *in vitro* fertilization was first described by Bavister et al., who subsequently provided the first report of the birth of a rhesus infant following transfer of cleavage stage embryos generated by *in vitro* fertilization. Since these initial studies, numerous laboratories have reported successful IVF in nonhuman primates, mostly with rhesus macaques.

In spite of the wealth of information available from experimental studies with nonhuman primates and other animals, the practice of IVF in humans remains inefficient. In the year 2000, the average clinical pregnancy rate (CPR) and live baby rate (LBR) in the United States were 38 and 33% respectively, which is approximately the same as rates reported for natural conceptions. However, it can be estimated that an average of three embryos was transferred in each treatment cycle; thus, the actual CPR and LBR rates per embryo transferred were 13 and 11%, respectively. Although other factors are involved, these rates suggest that the average quality of embryos produced in human IVF is low, and defects in oocyte are suspected to play a major role in this. Stimulating the ovaries with exogenous gonadotropins greatly increases the number of oocytes available for IVF, from the normal number of 1 or 2 up to 20 or so, but the quality and competence of these cohorts of oocytes are quite variable. In laboratory animals and other species, ovarian stimulation with exogenous gonadotropins (''superovulation'') reduces the average viability of embryos. This is because superovulation rescues some potentially atretic follicles containing defective oocytes.

The inherent variability of oocyte quality in humans is exacerbated by a wide variety of epigenetic effects on the oocytes and/or embryos resulting from IVF. These effects are due to exposure of oocytes and embryos to the artificial culture milieu that can alter gene expression, metabolism, mitochondrial localization and/or activity, and embryo development. On top of this, the quality or health of human oocytes is progressively diminished with increasing age because of inherent or genetic factors, manifested as reduced fertility and decreased success in assisted reproductive technology (ART). Other extrinsic factors such as nutrition, smoking, and environmental effects can all cause further reductions in the quality of oocytes and spermatozoa. More intensive research is needed to define the mechanisms by which epigenetic factors affect gamete quality, and to devise improved technologies for overcoming these deficiencies and for selecting the most viable gametes for use in clinical IVF.

4 Mitochondria

4.1 The Role of Mitochondria in ART

In spite of intensive research, the precise role of mitochondria in the development

of preimplantation mammalian embryos is still uncertain. Substantial changes in the organization and localization of active mitochondria occur during fertilization in some mammals. Pronounced morphological alterations take place early in embryogenesis that may reflect changes in mitochondrial metabolic functions. In addition, the numbers of mitochondria are substantially reduced during early embryo development.

Mitochondria are now recognized as a central factor in tissue biogenesis and as playing a key role in aging. Mitochondria are semiautonomous organelles each possessing one or more copies of their own restricted genome. In humans, this 16.6-kb circular strand of DNA encodes 37 genes including 13 components of the oxidative phosphorylation (OXPHOS) pathway, two ribosomal RNAs and 22 transfer RNAs. The vast majority of control genes for mitochondrial function, over 200, are found in the nuclear genome of the cell. Therefore, mitochondrial function is dependent upon the exchange of information between the cytoplasm and the nucleus. Mutations in both nuclear and mitochondrial genes have been associated with potentially lethal disorders affecting OXPHOS, prompting much interest in developing animal models to examine this disease process.

Replication and transcription of mtDNA is semiautonomous and requires interaction between the nucleus and the mitochondria. For example, mitochondrial transcription factor A (TFAM), a member of the high mobility group (HMG) of proteins, contains two HMG-box domains and is essential for the maintenance of mtDNA. Because it binds to mtDNA molecules, TFAM was first cloned and co-purified as a transcription factor. It is unlikely that TFAM or mtDNA molecules exist in an unbound form in the mitochondria. TFAM is sufficiently abundant to wrap mtDNA entirely, suggesting that human mtDNA is packaged with TFAM. The 25-kDa TFAM protein is translated from a nuclear gene whose primary function is to regulate the mitochondrial transcripts for both the heavy strand promoters (HSP) and the light strand promoters (LSP). TFAM is thought to enhance transcription via interaction with other factors such as DNA polymerase, which is the polymerase specific to the mtDNA and the nuclear transcription factor 1 (NRF-1). Both transcription factors are essential for replication of mtDNA. Consistent with this notion, low levels of mitochondrial TFAM (mtTFAM) are associated with mtDNA depletion and several severe mtDNA diseases. Targeted disruption of mouse TFAM or NRF-1 genes cause lethal mutations resulting in depletion of mtDNA during embryonic stages. Binding of NRF-1 is important for mtDNA activity *in vitro*, and its disruption leads to reduced expression of mtTFAM and mtDNA copy number. Therefore, studying mRNA profiles relevant to mitochondrial transcription factors such as TFAM and NRF-1 is necessary for understanding replication and transcription of the mitochondrial genome as well as other aspects of mitochondrial biogenesis. The need to understand the close harmony and complex mechanisms that exist between nuclear and mitochondrial genomes is important in the context of development of more aggressive forms of ART such as cloning and ooplasmic transfer. Apart from the problems that arise from genetic reprogramming of paternal and maternal imprinted genes, the requirement for strict concordance between the two genomes may lead to problems after nuclear transfer since we must consider the specific mitochondrial haplotype of the

recipient cells in relation to the inserted nuclei.

Maternally inherited mtDNA defects can result in debilitating or lethal conditions for affected individuals (so-called mitochondrial genetic diseases) if genes coding for respiratory chain enzymes are involved (OXPHOS diseases). For the oocyte and early embryo, it has been proposed that mutations in the mitochondrial genome may contribute to impaired function and developmental incompetence. The extent to which specific mtDNA defects are related to early reproductive failure is not clear, but genetic mutations may result in diminished ATP content leading to embryonic abnormalities such as cleavage arrest, slow development, blastomere loss by apoptosis, and, ultimately, implantation failure. As described below, the mitochondrial complement in human oocytes can be in excess of 150 000 organelles, so any potential adverse affect of mtDNA mutations associated with respiratory function would depend upon the magnitude of the mutant population (mutant load). It has also been suggested that embryonic failures could be a consequence of asymmetrical mitochondrial distribution in the pronuclear embryo. This could lead to disproportionate mitochondrial inheritance and perhaps produce blastomeres with diminished ATP generating capacity that could reduce developmental competence. Although it is generally assumed that mitochondria are critical determinants of competence, it is not known to what extent differences in early human embryo development observed within and between cohorts are associated with mitochondrial distribution and metabolic capabilities.

It has long been thought that the transmission of mitochondria between generations is strictly maternal. However, the development of more invasive techniques of assisted reproduction has increased concern that the mechanisms of uniparental (maternal) mitochondrial inheritance may be altered and as a result, the genetic integrity of the offspring could be compromised. For example, there is evidence of the persistence of human paternal mtDNA in ''abnormal'' unfertilized oocytes and embryos. Whether human sperm mtDNA is entirely eliminated or whether certain embryos are incapable of destroying sperm mitochondria is unknown. It is unclear whether the detection of paternal mtDNA sequences at extremely low levels is of any biological significance or simply coincidental and unrelated to embryo competence. With current experimental efforts designed to evaluate the potential therapeutic applications of nuclear and cytoplasmic transplantation for curing inheritable mitochondrial disease or known chromosomal abnormalities, it is necessary to understand the role(s) of mitochondria and the mechanisms that regulate their function in early mammalian embryogenesis. An understanding of the regulation and function of mitochondria in early human development becomes especially relevant in clinical IVF due to recent reports of three children born after interooplasmic transfer (insertion of a small amount of cytoplasm from an oocyte of a young woman into the oocyte of an older woman). In these children, a significant expansion of donor mtDNA has occurred, resulting in two genetically distinct populations of mtDNA coexisting within the same cytoplasm, a condition known as heteroplasmy.

The issue of concordance between the mitochondrial and nuclear genomes must be considered in light of the developmental

paradox regarding the transmission of paternal mitochondrial DNA, or lack thereof, in mammals. The fertilizing spermatozoon introduces up to 100 functional mitochondria into the oocyte cytoplasm at the time of insemination. However, these paternal mitochondria typically do not persist beyond early embryonic stages. It is presumed that there is mandatory destruction of the sperm mitochondria that appears to be evolutionarily and developmentally advantageous because the paternal mitochondria and their DNA may be severely compromised because of high levels of mitochondrial deletions and point mutations generated by the action of reactive oxygen species created by the spermatozoa during spermatogenesis and fertilization. Therefore, it is believed that mitochondria are inherited via strict maternal pathways while sperm mitochondria are selectively destroyed during fertilization and early embryogenesis and/or diluted below detection threshold levels with maternal mitochondria. Although a number of studies support the notion that sperm mitochondria are selectively destroyed by the egg, the actual molecular and cellular mechanisms are not known. Sutovsky et al. suggested that prohibitin could be one of the substrates that mark sperm mitochondria for elimination by proteolytic enzymes within the oocyte. In mice, paternal transmission of mtDNA has been observed in first-generation offspring resulting from interspecific crosses, and the persistence of paternal mtDNA has been detected in some abnormal human blastocysts and polyploid embryos. Despite the incompetence of these embryos, it may be relevant to ask what are the cytoplasmic conditions that allow the persistence of paternal mitochondria in order to further our understanding of normal regulation of mitochondrial transmission. Another suggestion to account for the absence of paternal mtDNA in human offspring is segregation of paternal mitochondria into extraembryonic tissues that develop into the placenta. However, no viable hypothesis has been advanced to explain how such a selective mechanism could operate. While transmission of paternal mitochondria may be more common in ''poor quality'' oocytes and embryos, it remains to be determined whether detection of paternal mtDNA could be a useful marker of embryo competence.

Although it is generally assumed that paternal mtDNA transmission does not occur after normal fertilization, the use of more invasive techniques in clinical IVF such as ICSI, ooplasm transfer, and nuclear transfer may alter the strict maternal inheritance of mtDNA. Consider the case of a 28-year-old man with severe mitochondrial myopathy due to a novel 2-bp mtDNA deletion in the *mND2* gene that encodes a subunit of the enzyme complex of the mitochondrial respiratory chain. The mtDNA harboring this mutation was paternal in origin and accounted for 90% of the patient's muscle mtDNA. The occurrence of paternal mtDNA in this patient may be an exceptional or unique situation resulting from the survival of some sperm mitochondria that ordinarily would never have been recognized had the pathogenic mutation not conferred an apparent selective proliferative advantage. While this case is assumed to be atypical, it is also apparent that underlying mechanisms responsible for elimination of sperm mtDNA in normal embryos are currently not well understood. As a consequence, further investigation of paternal mtDNA transmission and inheritance is critical if certain methods of nuclear or cytoplasmic transfer are to be used in assisted reproduction with any assurance

of safety. Furthermore, there is increasing evidence that mtDNA anomalies in spermatozoa may be associated with infertility. For example, mitochondrial point mutations and deletions have been correlated with poor sperm quality. It is unknown whether mitochondria of such spermatozoa, if introduced into an oocyte by ICSI, are eliminated in the same way as in their normal counterparts. If not, it is an open question as to whether mitochondrial diseases could be unknowingly transmitted by this method of fertilization.

4.2 Mitochondrial Inheritance following Ooplasmic Transplantation

As new technologies have been introduced and offered to patients seeking assisted reproduction, there is always considerable debate regarding the safety and efficacy surrounding these procedures. For example, the use of ooplasmic transfer has generated much attention. Ooplasmic transfer was developed to treat infertility patients with persistent poor embryonic development and recurrent implantation failure after IVF. In this experimental procedure, 5 to 15% of the ooplasm from a presumably fertile donor oocyte is microinjected into a compromised recipient oocyte. Transfer of small amounts of donor ooplasm introduces cytoplasmic proteins, mRNAs, small molecules, mitochondria, and other organelles into the recipient oocytes. Although the donor mtDNA may play no role in rescuing poor quality oocytes, ooplasmic transplantation clearly generates a mixture of mtDNA from two different parental origins (heteroplasmy) in any resulting embryos.

In two reports, relative proportions of donor and recipient mitochondria were assayed in embryos, amniocytes, fetal tissues, and blood using real-time qualitative fluorescent DNA sequencing. Donor mtDNA was detected in samples with the following frequencies: embryos 59.3%, amniocytes 22.2%, and fetal cord blood 25%. Recently, scientific attention has focused on the fact that three children produced by ooplasmic transplantation possess mitochondrial genetic material from two maternal sources, suggesting that donor mitochondrial populations not only persist but replicate in the developing children. Since the mitochondrial fingerprinting technique only qualitatively evaluates the presence of mtDNA heteroplasmy in these children, a sensitive, quantitative, allele-specific molecular beacon analysis was employed to document these changes accurately. The quantification of donor mitochondria in samples from three children using this method has shown that the donor mtDNA level is over 30% in the blood of these children and differs from the levels found in fetal cord blood and placenta in each case. Abandoning ooplasmic transfer as well as nuclear transfer in human IVF clinics has left many unanswered questions. Therefore, experimental studies on mitochondrial inheritance using nonhuman primates may be the best way to answer important questions concerning mitochondrial transmission, such as: (1) What is the normal level of heteroplasmy in primates? (2) Is there strictly uniparental, maternal mitochondrial inheritance using the IVF procedure? Nonhuman primates can answer questions concerning triparental inheritance whether the source is from paternal, maternal, or donor nuclei since we can manipulate oocytes and spermatozoa both inter- and intraspecifically within a controlled experimental environment. (3) How specific is

the elimination of the paternal genome via the ubiquitination process? (4) What changes occur in mitochondrial transmission after more aggressive assisted reproductive techniques such as nuclear transfer using blastomeres and eventually somatic cells as the donor cell source? This leads us to examine the fundamental problems associated with sophisticated ART procedures and compel us to revisit the issues of mtDNA transmission, the role of mitochondria in postfertilization development and more specifically, nuclear-mitochondrial communication.

5 Summary and Conclusions

The molecular basis of fertilization is still poorly understood. It is impractical to examine fertilization *in vivo*, so IVF is the best way to provide information, bearing in mind that events may not be identical to those occurring *in vivo*. Fortunately, the technology for achieving IVF is well developed for many species including humans and other primates, so we can address key questions about mechanisms and molecules. The advent of sensitive techniques such as RT-PCR and molecular beacon analysis compensates for the small amounts of material (oocytes and embryos) that are available. In particular, the normal events occurring at the molecular level during fertilization need further elucidation not only to further our knowledge but also so that any anomalies introduced by advanced ART can be analyzed and appropriate measures taken to avoid them. This should be the focus of future research investigations on mammalian fertilization.

Keywords

Amplification Inhibitors
Compounds in clinical specimens may inhibit amplification by reducing enzyme activity (DNA polymerase and/or DNA ligase), resulting in the occurrence of false-negative results.

DNA Polymerase
A thermostable DNA polymerase allows primer annealing and filling in of the gap at a higher temperature in G LCR. This increases specificity and eliminates the need to add additional enzyme following each cycle of denaturation.

Gap
Primer sets are chosen to anneal side by side to a single denatured template DNA target strand with a short gap of a few bases between the 3′ end of the first primer and the 5′ end of the adjacent primer. The gap consists of three or fewer of the four possible bases. This gap is filled in by the thermostable DNA polymerase. Since fewer than all four nucleotides are provided, the gap is precisely terminated at the beginning of the downstream probe. The resultant nick between the two annealed primers is sealed by DNA ligase.

Ligation
Formation of a covalent link between two immediately adjacent oligonucleotides annealed to a target strand of DNA by a thermally stable enzyme, DNA ligase.

Microparticles
Use of a carbazole label on the first probe and an adamantane label on the second probe allows for ligated probe capture with anti-carbazole microparticles and detection with anti-adamantane alkaline phosphatase. Microparticles with alternate surface chemistry have also been used by Abbott Laboratories in an automated system for purification of nucleic acids from clinical specimens.

Probe Amplification
Ligase chain reaction (LCR) is a nucleic-acid amplification technique in which sequential rounds of template-dependent ligation of four oligonucleotide probes result in the exponential synthesis of probes.

Ligase Chain Reaction (LCR) is a highly sensitive method for detecting nucleic-acid sequences. The LCR uses two pairs of oligonucleotide probes to hybridize to denatured target DNA strands. The positive-strand probe pairs are designed to bind immediately adjacent to each other on the target molecule. The negative-strand probe pairs bind similarly on the negative strand of the target DNA. A thermostable

DNA ligase is used to seal the nick between the annealed probes on each strand. Denaturation and annealing is achieved by varying the reaction temperature (thermocycling), and after strand separation, the newly ligated probe serves as a target template for subsequent reactions. Gapped LCR (G LCR) involves the use of DNA polymerase and DNA ligase to fill and seal a short gap between the annealed probes. In gapped LCR, the positive-sense probe pair binds to the target sequence, but they are separated by a few bases consisting of three or fewer of the four possible nucleotide bases. The negative-sense probe pairs bind similarly on the opposite-sense target strand. The thermostable DNA polymerase, provided with only a specific subset of the four possible nucleotides, extends the probe to a defined length until it is immediately adjacent to its downstream probe partner. The resulting nick between the extended probe and its partner is then ligated to complete the process. Similar to LCR, the newly ligated probe serves as a target template for subsequent reactions. GLCR has been commercialized for several microorganisms. The process can be qualitative and quantitative and has been shown to be more sensitive and specific than nonamplified assays for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* in traditional swab specimens and noninvasive clinical specimens such as urine. LCR assays have also been developed for other organisms such as *Mycobacterium tuberculosis*, human immunodeficiency virus DNA sequences, orthopoxviruses, human papillomavirus, herpes simplex virus, and hepatitis C virus RNA.

1 Principles of Ligase Chain Reaction (LCR)

Nucleic-acid amplification (NAA) assays have impacted the clinical microbiology laboratory by providing sensitive means of detecting specific nucleic acids. The amplification aspect of these assays has been achieved by a number of unique mechanisms including probe amplification, which is seen in ligase chain reaction (LCR). Unlike PCR where the target itself is amplified, LCR ligates two probes on each target strand. These ligated probes can then act as a template for subsequent cycles and can exponentially accumulate during the reaction. The principle of LCR is that two adjacent synthetic oligonucleotide probes anneal to a single strand of denatured target nucleic acid and are ligated to each other. LCR was first introduced in the late 1980s as the *ligase amplification reaction* and used sequential rounds of template-dependent ligation to identify specific nucleic-acid targets. Similar to PCR, LCR requires the use of a thermal cycler, detects DNA, and goes through a series of cycles for amplification to be achieved. Use of a thermostable ligase minimizes nonspecific interactions as ligation can be performed at or near the melting temperature (Tm) of the probes. Also, the thermostable ligase is able to maintain its activity even after multiple rounds of denaturation. The requirement of needing specific annealing of four oligonucleotide probes also increases specificity.

Achieving accurate results from LCR requires attention to primer design and reaction conditions. The melting temperature

of all four primers used should be within a narrow temperature range, ideally, 70 °C ± 2 °C, and having a GC basepair at the 3′ end of the first probe or at the 5′ end of the adjacent probe results in a stronger interaction, which leads to more successful ligation.

1.1 Amplification Steps/Probe Synthesis

Ligase chain reaction uses four oligonucleotide probes to recognize the target nucleic acid. In the standard LCR reaction, following a denaturation step, a pair of oligonucleotide probes anneal immediately beside each other on a strand of target nucleic acid. The second pair of probes anneals to the complementary strand in the same manner, leaving only a nick between the probes. The nick is sealed for each pair of probes with a thermostable ligase, and each newly ligated reaction product as well as the original target DNA can serve as template for subsequent cycles of denaturation, annealing, and ligation.

1.2 Gapped LCR (G LCR)

Gapped LCR (G LCR) is a modification of the standard LCR reaction that increases the specificity of the assay and reduces background due to blunt-end ligation (Fig. 1). The two pairs of oligonucleotide probes are designed to anneal to the template, with a small gap consisting of only three of fewer of the four possible nucleotides. The reaction mixture includes a thermostable DNA polymerase and the required subset of the four dNTPs. The thermostable DNA polymerase adds the specific dNTPs to fill the gap, resulting in an extended probe ending immediately adjacent to its downstream partner. The newly formed nick is then sealed by the DNA ligase. Nonspecific binding of the probes will not allow for ligation to occur. Other aspects of the amplification assay are unchanged.

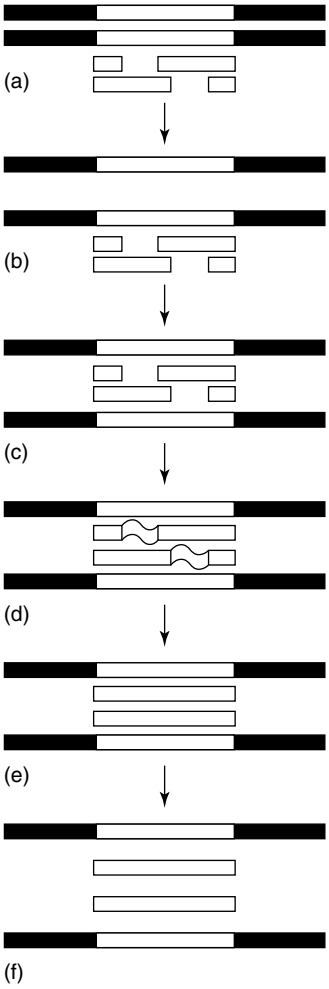

Fig. 1 Gapped ligase chain reaction amplification of DNA. (a) specimen with target; (b) heat to separate strands; (c) cool to allow probes to bind (d) PCR to fill gaps; (e) ligase to link two adjoining probes; (f) heat to separate new targets.

2 Techniques

2.1 Automation Methods

Automation has been a challenge for all NAA assays. The Abbott LCx system consists of a thermal cycler for amplification and a semiautomated enzyme immunoassay analyzer for detection of LCR or PCR products. Low-throughput manual specimen-preparation techniques have been superseded by higher-throughput systems that have employed several strategies. Abbott Laboratories has produced an M1000 automated system designed for the purification of nucleic acids from clinical specimens, using magnetic microparticles. The system uses uncoated iron-oxide particles to extract and purify viral RNA from clinical specimens, and reagent pipetting, heating, incubating, capturing, washing, and eluting do not require user intervention. HIV and hepatitis C virus (HCV) assays performed on the M1000 detected 50 to 1-million copies of RNA per ml and interfering substances were removed in the process. The process has also been demonstrated for DNA, using silica-based microparticles. Another approach has been to automate the specimen-pipetting component of sample preparation in the LCx Chlamydia assay by using a commercially available liquid-handling system called *Tecan Genesis RSP 100* (Tecan Inc., Research Triangle Park, NC USA). A mean time of 2.5 min was required to pipette a complete LCx assay carousel containing 20 samples and 4 controls, compared to 8.4 min manually, with equal precision and accuracy.

Other approaches have shown that pooling of swabs or urines in pools of four or eight have increased the number of specimens that could be processed for *C. trachomatis* and *N. gonorrhoeae*, maintaining good sensitivity and specificity and generating substantial cost savings (~50%) when the population tested has less than 10% prevalences of these two bacteria.

2.2 Detection of Amplified Product

Initial detection methods utilized a ^{32}P-label on the 3′ end of the upstream primer. The ligated product was separated from the nonligated primer by denaturing gel electrophoresis and the LCR product was detected by autoradiography. This detection procedure was followed by nonradioactive methods, one of which used fluorescent-labeled probes in a microtitre plate format. Detection of the fluorescently labeled LCR product was achieved using a fluorescent DNA sequencer and a Genescanner (Applied Biosystems). A less sophisticated nonradioactive method utilized one digoxigenin-labeled probe that was incorporated in the final LCR product and was detected by Southern blotting after separation by gel electrophoresis. An improvement for commercial applications is the Abbott LCx Analyzer, which incorporated microparticle enzyme immunoassay (MEIA). Use of a carbazole label at the 5′ end of the first probe and an adamantane label on the 3′ end of the second probe allows for ligated probe capture with antibody-coated anti-carbazole microparticles. The automation transfers the amplification product sample to a glass-fiber matrix to which the microparticle complexes bind the product irreversibly. A wash step removes unligated probe with only the detection label. The bound microparticle complexes are then incubated with alkaline phosphatase-conjugated antibody that

binds to the adamantane hapten. The complex is then detected by adding a substrate that is dephosphorylated to a fluorescent molecule by the alkaline phosphatase. The fluorescence rate is detected in the MEIA optical assembly in the LCx Analyzer. The presence or absence of specific target is determined by comparing the specimen result to the cutoff (CO) value. The CO value is the mean rate of LCx Calibrator duplicates multiplied by a factor determined in clinical studies (0.45 for *C. trachomatis*, 0.25 for *N. gonorrhoeae*). The sample rate/CO (S/CO) value is determined by calculating a ratio of the sample rate to the CO value. An S/CO ratio >1.0 indicates a positive LCx assay result.

3 Applications

3.1 Detection of *C. trachomatis*

The first use of LCR for amplifying *C. trachomatis* DNA appeared in 1993. After several years of improvement, the assay was quickly used in studies on clinical specimens and was made commercially available in 1995. The test demonstrated high sensitivity and specificity on cervical and urethral swabs compared to culture and detection of *C. trachomatis* antigens and nucleic acids by hybridization. These comparisons led to the conclusion that LCR and the other NAA assays were approximately 30% more sensitive than all other preexisting diagnostic technologies. The timely publications of the ability of LCR to diagnose *C. trachomatis* infections by noninvasive screening of female urine was rapidly confirmed by several authors. More recently, other noninvasive specimens such as vulva, introital, and vaginal swabs have been shown to be effective for *C. trachomatis* diagnosis using LCR. Other clinical samples now being pursued are pharyngeal, glans penis, rectal swabs, and synovial fluid.

3.2 Detection of GC

Birkenmeyer and Armstrong published the first evaluation of LCR for the diagnosis of *N. gonorrhoeae* (GC). Like the results achieved on clinical specimens for the detection of *C. trachomatis* nucleic acids, LCR clinical evaluations for GC on cervical and urethral swabs and urine have shown similarly high sensitivity and specificity. LCR has frequently diagnosed additional GC infections compared to culture. The LCR test has performed very well on vaginal swabs and extragenital specimens such as anorectal and pharyngeal specimens.

3.3 Detection of *M. tuberculosis*

Application of LCR for bacterial pathogens has not been limited to the STD pathogens; Iovannisci and Winn-Deen used LCR to detect the *M. tuberculosis* insertion sequence IS6110. Using fluorescently labeled probes and a fluorescent DNA sequencer, they were able to detect 100 copies of the target even in the presence of other exogenous nucleic acid. Ausina et al. described the first evaluation of a commercial LCR assay (Abbott Diagnostics) for direct detection of *M. tuberculosis* in respiratory specimens. The four primers recognize the *M. tuberculosis*-specific protein antigen b gene in a G LCR format, followed by detection using the LCx Analyzer. Similar to other commercial LCR assays, there are three main steps to the protocol: specimen preparation, amplification, and detection.

As a large proportion of respiratory specimens sent to the Mycobacteriology laboratory are sputums, specimen preparation in the *M. tuberculosis* assay has been modified. Pretreated SDS–NaOH (decontamination/mucous treatment) concentrates of respiratory specimens, which are used routinely for smear and culture detection of *M. tuberculosis*, are the starting materials for extraction. The specimen is further treated with lysis buffer and the mycobacterial DNA is released by mechanical lysis in the LCx Lysor. Extrapulmonary specimens have been evaluated in a number of studies, and sensitivities are similar to other amplification assays. The proposed use of this assay to identify *M. tuberculosis* from culture-positive bottles shows high sensitivity and specificity.

The Commercial Mtb LCx assay has been compared to other amplification methods, including PCR (COBAS AMPLICOR *M. tuberculosis* Test, Roche Diagnostics Systems, Brachburg, NJ) and Transcription-mediated Amplification (Amplified *M. tuberculosis* Direct Test, Gen-Probe, San Diego, Calif) on both respiratory and extrapulmonary specimens, and has demonstrated comparable sensitivity to other commercial assays. There are two reports of a specific isolate of *M. tuberculosis* not being detected by the LCx assay. Further characterization of the isolate in one of the studies indicated that a deletion in the target region for the probes was responsible for the failure in detection. This appears to be a fairly rare incident; however, it should be considered when using the assay as a screening tool. Generally, this is a highly reliable assay on smear-positive respiratory specimens and a multicenter evaluation of the LCx assay suggested that the sensitivity of the assay might be improved with the inclusion of a gray zone.

3.4 Detection of Other Microorganisms

Although LCR assays have found their greatest application in detection of the STD organisms *C. trachomatis* and *N. gonorrhoeae*, and more recently, in the detection of *M. tuberculosis*, since its inception, the LCR has also been used for numerous other applications. Early viral targets for LCR assay development have included human immunodeficiency virus, human papillomaviruses, and herpes simplex viruses. Detection of other viral targets included an LCR reaction that was able to differentiate Cowpoxvirus from other Orthopoxviruses by targeting two adjacent nucleotides and an asymmetric G LCR to detect Hepatitis C virus RNA. Utilizing the unique ability of the G LCR to discriminate DNA sequence differences, Karthigesu et al. and Osiowy described the use of G LCR to identify Hepatitis B virus (HBV) surface gene variants. LCR was also used to detect HBV precore mutants. Mutations associated with antimicrobial resistance can also be detected using G LCR, as described for ganciclovir resistance in cytomegalovirus (CMV) and for characterizing eliminate SHV B-lactamases. Bacterial targets for LCR development have included *Borrelia burgdorferi*. The LCR assay has also been applied to the agriculture and environmental fields, with its use in the identification and discrimination of *Listeria monocytogenes* and *Erwinia stewartii*.

4 Perspectives

4.1 Specimen Preparation

Clinical specimens may contain intracellular or extracellular nucleic acids for detection in NAA assays. The relative

concentration of DNA and inhibitors of amplification and/or ligation may impact on whether the sample is recorded as positive or negative in the LCR assay. Specimen adequacy has been used to monitor positive or negative *C. trachomatis* results in cervical swabs. It has been postulated that higher reactive levels might be achieved in the *M. tuberculosis* LCR if greater amounts of DNA could be released from the bacteria. Each NAA test has the CO for positivity and negativity established by statistical calculation performed on dilutions of nucleic acids and large numbers of positive and negative clinical specimens. Levels are arbitrarily raised or lowered to yield optimum sensitivity and specificity. Each commercial assay is required to be reproducible, and therefore, strict adherence to defined specimen preparation is important. When an assay is used on a new specimen type, the results can only be trusted after appropriate validation has been achieved.

Inhibitors of the *C. trachomatis* LCx have been reported and have been found to be associated with female urinary substances. These studies should be interpreted with caution as it is recognized that inhibitors are detected by adding certain strengths of *C. trachomatis* DNA to specimens, and too little DNA suggests more inhibition and too much implies none. Added DNA may also be lost during processing creating ''false inhibition''. Reproducibility problems have been reported for the LCx *C. trachomatis* assay. This phenomenon has been mainly experienced on specimens near the test CO and is present with other amplification tests such as PCR.

4.2 Advantages

The advantages of LCR have been its clinical robustness in the LCx format. The assay is virtually without contamination in the LCx instrument. Small volumes of clinical specimens such as urine are used and samples are stabilized at ambient temperature for sufficient periods to allow mailed and home-collected specimens to yield positive results.

4.3 Disadvantages

The LCR can be susceptible to inhibitors in clinical specimens, requiring a removal maneuver early in the protocol. Low throughput in the existing instrumentation is a disadvantage, which may be addressed as discussed in Sect. 2.1 above.

Keywords

Metabolic Network
Graph structure that displays connected metabolic interactions in one or several organisms.

Molecular Docking
The computational analysis of the geometry and binding affinity of a complex to two interacting molecules.

Ontology
Structured vocabulary for talking about a specific subject, such as diseases or protein function.

Phylogeny
Mostly tree-like arrangement of several related molecules or species in order to display their evolutionary relationship.

Protein Interaction Network
Graph structure that displays pairwise interactions between proteins. The nature of the interactions can be diverse (molecular, genetic etc.).

Protein Structure Prediction
Computational generation of a three-dimensional model of a protein, given its sequence.

RNA Secondary Structure Prediction
Computational generation of a model of the base pairings in an RNA molecule.

Regulatory Network
Graph structure that displays connected protein interactions that regulate cellular processes such as gene expression.

Sequence Alignment
The stacked arrangement of several molecular sequences in rows such that matching characters in different sequences are arrayed below each other in columns. Sequence alignment is performed in order to display correspondences between characters in different sequences. Correspondences can be of an evolutionary or structural nature.

Text Mining
Automatic extraction of biological content from the computer-accessible literature.

Virtual Cell
Comprehensive computer model of the structure and inner workings of a cell.

In recent years, biological research is increasingly being based on large-scale experimentation that collects data on an organismic scale. These data are voluminous and often very noisy. Not just their interpretation but also the configuration of the involved experiments necessitates complex computer analysis. The respective computer methods are themselves an object of intensive research in a scientific discipline called *computational biology* or *bioinformatics*. Computational biology has a wide variety of facets ranging from experiment configuration and low-level data analysis to hypothesis generation by computer.

1 Introduction

The term *Bioinformatics* denotes the field that employs computer-based methods to investigate the molecular basis of living systems. The foundation for the field is provided by molecular biology data (molecular sequences, 3D structures of molecules and molecular complexes, data on mRNA and protein expression levels in cell etc.). The term *Bioinformatics* is used synonymously for the term *Computational Biology* in several countries. In the United States, Bioinformatics addresses more the infrastructural aspects of the field (accessibility of data and methods, data consistency and quality control, networking, etc.) while the scientific aspects are addressed by *Computational Biology*. Also, the term *Bioinformatics* suggests a focus on the molecular subcellular level, whereas *Computational Biology* is more open toward investigating higher levels of biological organization [1, 2].

Biology has experienced a dramatic shift in recent decades from a science that was mostly phenomenological and taxonomic in character to a field that, today, is mainly based on quantitative analysis. The molecular basis of living systems has moved more and more into the focus of biological research. In addition, in recent years, a type of experimentation has gained significance that aims at the large-scale collection of data. Rather than analyzing very local systems such as a single gene or protein and its effects, this type of experimentation, which is also called *screening*, aims at covering a substantial part or all data of a certain kind that can be obtained for an organism. The first screening projects addressed the genome sequence and started in the late eighties with the decision of the US Congress to sequence the complete human genome. It took roughly 15 years to complete this task. Along the way, the experimental technology had to be developed, and it was ''tried out'' on a series of more and more complex organisms (*see* Table 1 for the list of genomes whose completion marked the progress in genome sequencing technology). As this text goes to print, there are 209 published complete genomes (most of which are prokaryotic), and 956 genome sequencing projects are under way (See http://www.genomesonline.org/ for an up-to-date status of genome sequencing projects). The sequencing of small genomes does not involve major bioinformatics efforts (though the interpretation of the genome sequence does). However, as the genomes become larger and more complex, assembling the sequence data involves substantial bioinformatics. Major bioinformatics efforts were needed to assemble the genomes of *Drosophila melanogaster*, *Mus musculus*, and *Homo sapiens*. Section 2 of this chapter summarizes the bioinformatics needs of genome sequencing projects.

The availability of a complete genome sequence immediately raises a multitude of research questions that can be addressed with the help of bioinformatics methods. In Fig. 1, these questions are arrayed in order from the genotype (five o'clock direction) to the phenotype (counterclockwise up to the four o'clock direction). Some of these questions can be addressed without resorting to additional experimental data; for other questions, additional experimental data are needed. We will now quickly review these questions and go into more detail in the succeeding sections.

Tab. 1 Landmark genome sequencing projects.

Organism	*Colloquial name*	*Genome length (in kb)*	*Date sequenced*
Haemophilus influenzae	Bacterium (ear infections)	1830	1995
Escherichia coli (K12)	Bacterium in the intestine	4639	1997
Saccharomyces cerevisiae	Bakers yeast	12 069	1997

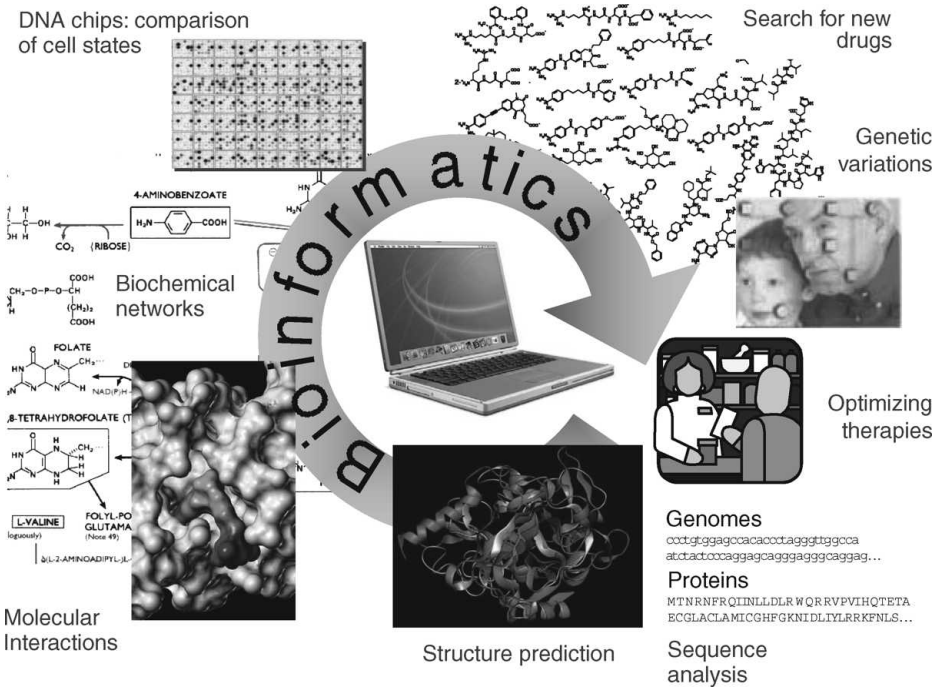

Fig. 1 Bioinformatics – from the genotype to the phenotype.

Among them are the identification of genes in the genome sequence and the analysis of noncoding regions (Sect. 3). The prediction of protein structure from protein sequence is another important problem that deserves a separate section (Sect. 4). The analysis of molecular interactions on the basis of the structure of the involved molecules is the foundation for understanding binding properties, and also serves as a starting point for drug design. We detail this field in Sect. 5. Processes of life are composed of complex biochemical networks made up of pathways and cycles of intermolecular interactions. The bioinformatics analysis of these networks is the topic of Sect. 6.

Since all cells of an organism have the same genome, we need additional data in order to differentiate between different tissues and cell states. mRNA expression data are a current-day approach to measuring this kind of information. Section 7 discusses bioinformatics methods for analyzing these data. The determination of protein function is the Holy Grail of modern biology, in general, and of bioinformatics, in particular. Protein function signals are contained in many diverse biological data. Thus, protein function prediction is an integrative task, which will be discussed in Sect. 8. Section 9 summarizes bioinformatics approaches to analyzing genetic variations in organisms, both in the human and in its microbial and viral parasites and infectious agents. Section 10 comments on the basic information infrastructure technologies relevant to bioinformatics. Finally, Sect. 11 wraps up this chapter with a general appraisal of the potential and limitations of bioinformatics.

2 Sequencing Genomes

The basis of the bioinformatics support for sequencing genomes is quickly explained. Experimental methods for genome sequencing can only handle a sequence of a few hundred base pairs length at a time. Therefore, the genomic or chromosomal sequence has to be cut into fragments of about that length before sequencing can begin. (The fragments can be longer, but then only their ends can be sequenced.) After the fragments have been sequenced, the original genome sequence has to be pieced together from the fragments. It is this assembly process that requires critical bioinformatics support.

The basic fragment assembly problem is quite simple. The sequencing process generates multiple coverage of the complete genome sequence (or of a well-defined part of it that has been identified in the previous process of constructing a physical map of the genome) with small fragments of several hundred base pairs in length. The coverage of the genome sequence must be sufficient to ensure with high probability that the segments overlap along the complete genome sequence (e.g. for the human genome, a coverage of 7X was required [3]). The fragment assembler then aligns the fragments by comparing their sequences to form the complete genome. If adjacent fragments are unique and overlap along a stretch of sufficient length, then the alignment is also unique. The only variations between different fragments covering the same part of the genome sequence can originate from reading errors or polymorphisms (in a heterozygous individual) and there are only a few of those. Therefore, the alignment problem is much simpler than the alignment of different (especially of evolutionarily only distantly related) sequences. Fragment assembly experiences its major complication by the occurrence of long repeats in the genome sequence. It is evident that in the presence of repeats the fragment assembly process just described is corrupted. For a more detailed overview of fragment assembly, *see* [4].

Fragment assembly has experienced its culmination and most dynamic progress in the process of sequencing the human genome. The human genome was sequenced by two different groups concurrently that used different experimental procedures. Both groups presented a draft of the human genome sequence in February 2001.

The method used by the public consortium is sometimes called *hierarchical*

shotgun (HS) sequencing [5]. Using this method, genomic DNA is cut into fragments by partial digestion with restriction enzymes. These fragments are then used to produce libraries of BAC (bacterial artificial chromosome) clones. These clones are between 150 and 200 kb in length. A physical map of these BACs is constructed in order to identify those clones that minimally overlap and are therefore suitable for sequencing. The selected BACs are subcloned into shotgun libraries (libraries of short randomly cut pieces of the clone) and sequenced. Finally, the genome is reconstructed using data from the overlapping sequences, guided by the map. The HS approach provides an accurate finished genome, but requires substantial additional preliminary laboratory work in creating the BAC libraries. The draft assembly of the public consortium was computed by Jim Kent at the University of California, Santa Cruz [6].

An alternative method, used by Craig Venter's group at Celera Genomics to provide a draft sequence of the human genome is whole-genome shotgun (WGS) sequencing [3]. In this approach, shotgun sequencing is applied to the whole genome, by directly sequencing clones that are 2, 10, and 50 kb in length. Additional information comes from known markers, which are used for anchoring assembled contigs (continuous stretches of sequences arising from overlapping clones) to the genome. The genome assembler for Celera was written by Gene Myers and his bioinformatics team [7, 8]. (Other algorithms for fragment assembly in shotgun sequencing have been presented in [9, 10].)

In general, the choice of the sequencing method depends on the complexity of the genome under study and the desired level of completeness of the genome sequence. The WGS approach is well established for shorter genomes without many repeats, especially for prokaryotic genomes. For long and repetitive genomes, the WGS approach is effective in obtaining a draft covering, say 80%, of the genome sequence. Finishing sequencing of a genome is difficult with this approach.

The WGS approach was since applied to drafting the dog genome [11] and probes from the Sargasso Sea containing many organisms [12]. A hybrid approach, which utilizes aspects of both methods, was used for finishing the human and the mouse genome [13]. The public consortium finished the human genome sequence in April 2003.

3 Molecular Sequence Analysis

There are a wide variety of questions that one can ask about a genome sequence. There are low-level analyses, such as analyzing the information content of a sequence or finding repetitive patterns and high-level analyses such as finding genes and analyzing the upstream regulatory regions. There are widely used packages for performing a variety of low-level and high-level analyses, such as the GCG Wisconsin package [14]. In this section, we will only address the most important and widespread sequence analysis problems.

3.1 Sequence Alignment

The most basic sequence analysis method is that of sequence alignment. Sequence

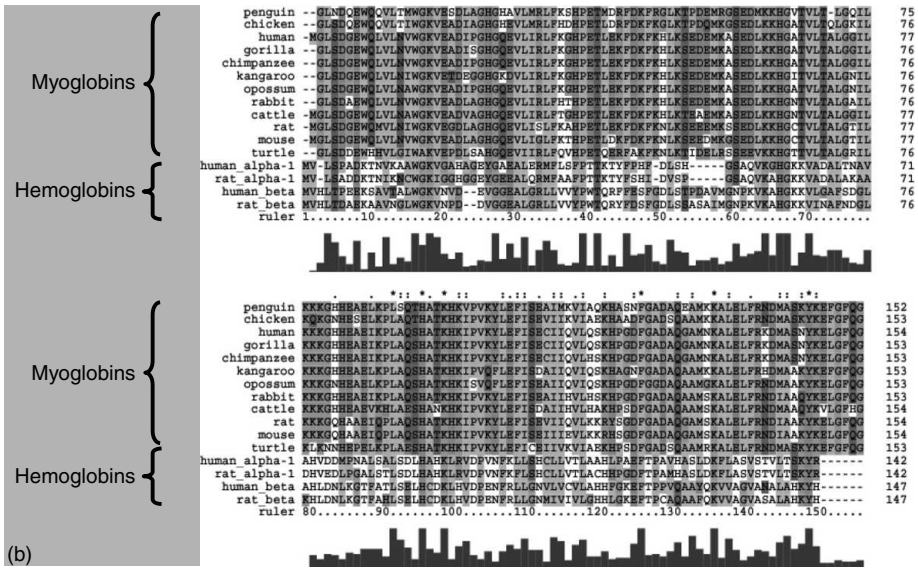

Fig. 2 (a) Global alignment of the human hemoglobin α_1 and hemoglobin β sequences. The numbers at the left and right side of the alignment represent sequence positions at the end of each row. The signs in the middle row signify similarity between the matched amino acid residues: | identical, : similar,. not similar. (b) Multiple alignment of several myoglobin and hemoglobin sequences. The alignment was generated with ClustalW. The colors represent chemical groups of amino acid residues. The bar graph at the bottom of the figure represents the degree of conservation of the respective alignment columns.

alignment arrays two (pairwise alignment) or more (multiple alignment) similar nucleic acid or protein sequences such that corresponding nucleotides and amino acid residues respectively are matched to each other. *Correspondence* can mean different things, in this context. Often, we mean *evolutionary* correspondence in the sense that the two monomers matched have the same evolutionary origin. But sometimes we will also mean *structural* correspondence in the sense that the two matched monomers play the same role inside the molecular structure. The sequence alignment method can be applied to DNA, RNA, and protein sequences alike. Figure 2(a) shows an alignment of the human hemoglobin α_1- and β-chains. Figure 2(b) depicts a multiple alignment of myoglobin and hemoglobin sequences

from different organisms. The additional gap character (-) serves to introduce insertions and deletions during the alignment such that corresponding positions in the different sequences match each other. There are exponentially many alignments in n and k between k sequences of length n. In order to find the desired alignment, we attribute a cost to each alignment. Then, we look for the alignment with maximum or minimum cost, depending on the scoring function used. Let us discuss cost maximization of a pairwise alignment of protein sequences, for concreteness. Then the cost function is a sum of terms. There is a term for each alignment column that does not contain gap characters (match/mismatch terms), and there are terms penalizing for gaps (gap terms). The cost terms are usually derived statistically. In the evolutionary interpretation of the alignment score, the match/mismatch terms are collected in a so-called substitution matrix and reflect the expectation to see the mutations witnessed by an alignment column. A basic simplifying assumption is that the mutations witnessed by different alignment columns are independent. This results in quite efficient alignment algorithms that are based on the dynamic programming paradigm [15]. The gap terms are usually set heuristically or by fitting them to a dataset of accepted alignments [16]. Pairwise alignments can align complete sequences (global alignment) and they can be used to find shorter sequence fragments in longer sequences (local alignment). The runtime of the alignment algorithm grows linearly in the product of the length of the two sequences to be aligned. If one wants to screen against a large database of sequences, even this is too much. Then one resorts to faster heuristics that are based on gapless alignment of locally similar stretches. The most widely used alignment program BLAST is based on this approach [17]. It owes its popularity not only to its efficiency but also to the fact that it returns a significance value (p-value) with the alignment that quantifies how improbable it is to observe the sequence similarity witnessed by the alignment. The more improbable an alignment, the smaller is its p-value and the more significant the finding. BLAST is probably the only major bioinformatics tool, which returns a significance value that is based on solid statistical theory [18].

Multiple alignments are harder to optimize than pairwise alignments. The straightforward extension of the pairwise gapped alignment algorithm leads to an exponential procedure and raises the problem of having to derive many cost terms based on scarce data. These problems can be circumvented, by using heuristics. PSI-BLAST [19] uses a heuristic based on BLAST in order to find sequences related distantly to a query sequence and align them multiply. PSI-BLAST takes a query sequence and computes a multiple alignment of sequences taken from a sequence database. A statistically well-founded approach to multiply aligning n given query sequences is provided by the so-called Hidden Markov models (HMMs), a stochastic procedure by which a certain Markov chain is trained to a family of related protein sequences. The result is a probabilistic weighting of the state transitions and output behavior of the Markov chain that causes it to generate new sequences of the same protein family with significantly higher probability than other sequences. This chain can then be used to multiply align protein sequences of that family and decide whether new chains belong to the family or not [20]. With HMMs, an alignment of k sequences of length n can be obtained in time $O(kn^2)$. Other very

popular multiple alignment programs are ClustalW [21, 22] and T-COFFEE [23] (*see also* Sect. 3.2). Databases of manually curated multiple alignments can be used to benchmark alignment methods [24, 25].

Sequence alignments are the basis of analyzing relationships between DNA, RNA, and protein sequences, respectively. On the DNA level, alignment algorithms are used to find genes [26] and analyze regulatory regions [27]. On the protein level, the relationships to be searched for can be evolutionary [28–30] or structural [31, 32]. The description of the kind of relationship looked for is contained in the scoring matrix. Whereas early approaches used the same amino acid–substitution matrix for all alignment columns, newer approaches use so-called position-specific scoring matrices (PSSM), that is, they adapt the scoring matrix to the specific needs of an alignment column. For example, in a structure alignment, each column stands for a local structural neighborhood in the two proteins to be aligned. This neighborhood has specific features that can be reflected by a scoring matrix tailored to this neighborhood. The same phenomenon can be taken into account, when aligning DNA sequences of upstream regulatory regions of genes, in order to find binding sites for transcription factors. Therefore, position-specific scoring matrices are used in this context, as well [33, 34]. HMMs are the basis of a number of protein family classifications [35–37], and they have also been applied to gene finding and to the analysis of promoter regions [38].

3.2 Phylogeny Construction

In phylogeny construction, one is interested in learning about the evolutionary relationship of a set of sequences. The basic idea is to generate a tree whose leaves are the sequences to be related and whose edges have appropriate lengths such that the unique path between two sequences in the tree approximates the respective evolutionary distance as accurately as possible. Figure 3(a) shows a phylogenetic tree of the myoglobin sequences used in Fig. 2(b). It is desirable to annotate the interior vertices of the tree with ''ancestral'' sequences such that the sequences that annotate the vertices adjacent to an edge align with a score that equals the length of the edge. Then the tree corresponds to a multiple alignment of the given sequences and the inferred ancestral sequences.

There are several ways of constructing a phylogenetic tree. One approach is *distance-based*. Here, the evolutionary distance between two sequences can be represented by the score of their pairwise alignment or by some other measure of similarity (e.g. the distance can be estimated with a maximum-likelihood method). A tree is searched for that best approximates the resulting distance matrix of the set of sequences involved. The optimization problem of finding a tree that best fits this distance measure given by the pairwise alignments of the sequences to be related, is difficult (NP-hard) and thus can only be solved approximately [15]. The problem of finding such a tree is intimately related to the problem of finding a high-quality multiple alignment of the set of sequences. Thus, there are also methods that combine these two tasks. For instance, ClustalW (see also Sect. 3.1) constructs a multiple alignment and a phylogenetic tree bottom-up by successively clustering sequences that are most closely related. The interior nodes of the tree are annotated with sequence profiles that give the preferences for amino acids (or nucleotides)

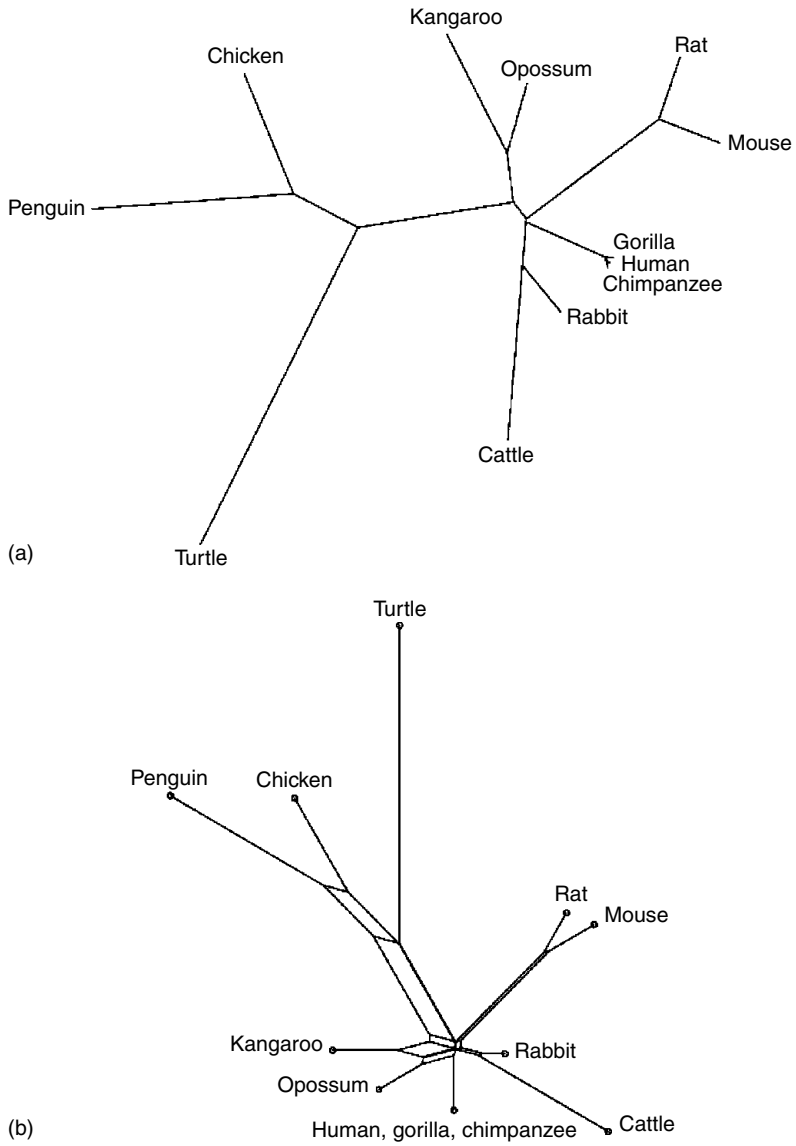

Fig. 3 (a) A phylogenetic tree of the sequences aligned in Fig. 2(b). (b) A split diagram of the more closely related sequences from Fig. 2(b).

at each position in the respective cluster. These profiles can be turned into ''ancestral'' sequences with consensus methods.

The *maximum parsimony* approach aims at inferring a tree that explains the evolutionary relationship between a set of sequences by introducing as few mutations as possible. This is a strong assumption that is not realized by nature in general but serves to simplify the

problem of generating phylogenies. The *maximum likelihood* approach is based on a probabilistic model of evolution and aims at generating the phylogeny that is most likely, given the observed data. It is generally much more time-consuming than the other approaches but has the advantage of being founded on a statistically more sound and generalizable theoretical basis [39].

PHYLIP (http://evolution.genetics.washington.edu/phylip.html) and PAUP* (http://paup.csit.fsu.edu/) are two widely used software libraries for constructing phylogenies (For a list of phylogeny programs, see http://evolution.genetics.washington.edu/phylip/software.html).

Phylogenies are hard to validate, because the biological process that generates phylogenies is hard to model and observe. This process has two players, namely, the stochastic process of *sequence variation* and the highly complex and unstructured process of *selection*. Because of the complexity of this situation, each accepted phylogeny is the result of a consensus among biologists rather than an imperative consequence of the given sequence data. Specifically, (a) the alignment score reflects evolutionary distance only incompletely and (b) the hypothesis that the phylogeny is tree shaped is not valid in many biological settings, for example, because recombination events can take place. The split-decomposition method [40] takes account of the fact that the distance measure derived from the sequence alignments need not be treelike. The method generates so-called split diagrams that are more treelike if the underlying distance measure allows for this, but that show deviation from the tree shape where they occur. Figure 3(b) shows a split diagram of the myoglobin sequences from Fig. 2(b).

A comprehensive up-to-date overview of methods for constructing phylogenies is given in [41]. A short recent overview can be found in [42].

3.3 Finding Genes

Finding genes is one of the grand challenges of computational biology. Figure 4 depicts the structure of a eukaryotic gene. Identifying genes entails the elucidation of all parts of the gene, not just the coding regions. Exons have to be distinguished

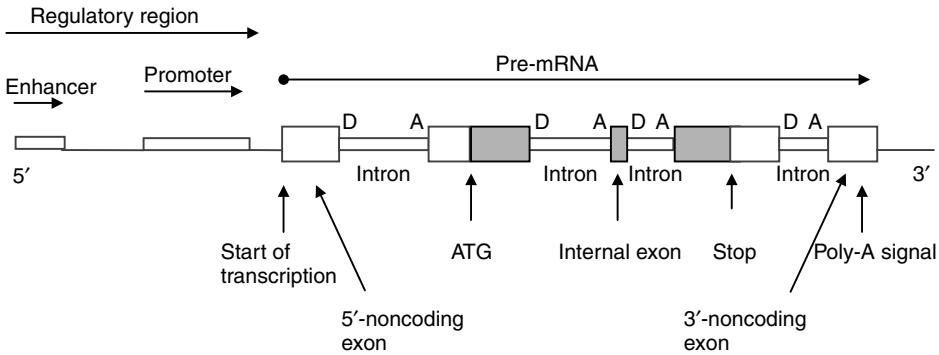

Fig. 4 The structure of a eukaryotic gene. Only the shaded parts represent coding regions.

from introns; transcription and translation, initiation and termination sites have to be identified.

There are basically two different approaches to identifying genes in genomic sequences, *content sensors* and *signal sensors* [43]. Content sensors aim at classifying DNA segments into types such as coding and noncoding. The so-called *extrinsic* (or *homology-based*) content sensors do this by comparison of the DNA sequence with biologically confirmed known gene sequences. Sequence alignment methods are used for this purpose. With the growing number of genomes, one can try to use this approach to render the gene finding procedure more accurate [44] or even to capture aspects of the evolutionary development of genes [45]. If sequences similar to the query sequence are not available, one has to distinguish the gene regions on their own right, that is, by *intrinsic* properties of short sequence fragments such as compositional bias or codon usage (*de novo* approaches). Statistical classifiers use these properties as input and are trained on biologically characterized sequences (*see* e.g. [46, 47]). HMMs are also used to model intrinsic properties of gene sequences [48].

The signal sensor approach tries to locate functional sites in genes such as splice sites, binding sites for transcription factors, and so on. A popular approach is to describe the neighborhood of a functional site with a position-specific weight matrix that is trained on a multiple alignment of the neighborhoods of confirmed functional sites [49, 50]. The alignments used for deriving such matrices are gapless. By using HMMs, one can introduce gaps in the respective alignment [50]. In fact, most of the current-day programs for finding functional sites use this technology.

The accuracy of gene prediction programs can be measured on the nucleotide and on the exon level [51]. For mammalian sequences, the accuracy of the best gene prediction programs in correctly predicting coding nucleotides is above 90%. On the exon level, the accuracy is markedly lower. Less than 80% of the exons had all their exon boundaries predicted correctly. The correct prediction of complete genes is even lower: less than 50% of predicted genes correspond exactly to the actual genes [52, 53]. The problem lies in predicting the exact limits of the coding regions. Also, gene prediction accuracy drops dramatically as the density of genes decreases and the introns become longer. Overall, exact gene prediction is still an unsolved problem.

3.4 Analyzing Regulatory Regions

Regulatory regions are the regions in DNA that lie in the (mostly upstream) neighborhood of the genes and that contain binding sites for the transcription machinery that is responsible for expressing the gene. Therefore, these regions harbor crucial information on the regulation of gene expression. Polymorphisms in these regions are responsible for many of the small and large differences between organisms of the same species and also for many predispositions and diseases. Thus, their understanding is of great importance. The most intensively studied regulatory regions are the promoters that harbor the binding sites of transcription factors (TF). Promoters exhibit a modular architecture, that is, they are composed of several TF-binding sites. Each binding site is a short segment of DNA (length 10 to 15 kb), and different binding sites are located at

varying distances to each other. The characteristics on each of the blocks can be captured with a weight matrix (see also Sect. 3.3). The modular architecture has to be captured with specifically tailored organizational models. Today, such models tend to be tailored to specific classes of promoters and are not generally applicable. Therefore, statistical methods that analyze intrinsic sequence properties are also employed [27]. The methods used are not unlike those for gene identification. Since TF-binding sites are short and highly conserved, a special approach to finding them is based on the analysis of almost identical short sequence segments in a set of DNA sequences [54, 55]. The methods used in practice today are reported to find up to about half of the existing promoters but output a significant number of false positives [56].

Enhancers, silencers, and matrix-attached regions are other types of regulatory regions that are attempted to be predicted with similar technology. Compared to protein-based bioinformatics, the analysis of regulatory regions is still in an early stage of development. It is especially difficult because the processes of molecular recognition based on proteins binding to DNA are very intricate and cannot be analyzed on a structural level yet. Thus, we have to derive all information from the rather indirect methods of sequence analysis and comparison.

3.5 Finding Repetitive Elements

As we have already seen in Sect. 2, repeats are a characteristic and complicating feature of many complex eukaryotic genomes. They present a problem with genome assembly, but they also require specific methods of sequence analysis. A few programs have been developed specifically to find different kinds of repeats in genomes.

The function of repeats in genomes is not yet well understood. Palindromic repeats (those where a sequence and its reverse complement are arranged back to back) may point at structural features such as hairpins in RNA. Repeats also have been shown to affect bacterial virulence in infectious diseases.

There are a variety of repeat finding programs. The most obvious kind is based on the observation that repeats tend to throw off sequence analysis programs; thus, they are located and masked out in the first step. Repeat masking programs such as RepeatMasker (http://ftp.genome.washington.edu/RM/RepeatMasker.html) use a dictionary of known repeats and find all exact or approximate matches to the dictionary entries in the genome sequence under investigation.

Repeat masking programs can only rediscover repeat patterns. A more challenging task is to find repeats, just given the genome sequence.

A very important subtype of repeats is tandem repeats. Here, two exactly matching short sequences immediately follow each other. There are programs that specialize in finding tandem repeats [57].

The largest challenge is to find general repeats without prior knowledge, just using the genome sequence as a basis. Such programs usually find exact repeats in a first step. These are then used as seeds for finding so-called degenerate repeats that are similar but not exactly alike. The programs REPuter [58] and MUMmer [59] store the genome sequence in a data structure called a *suffix tree* that enables the fast identification of exact repeats. The FORRepeat program uses so-called *factor oracles* for this purpose. An important

feature of repeat finding programs is an effective visualization of the output.

Repeat finding programs can be exercised for a multitude of tasks. (1) Checking genome assemblies. Assembly programs (Sect. 2) are imperfect and thus the sequence assemblies they produce may contain errors. Repeat finding programs have detected palindromic repeats in the human genome sequence that were due to wrong assembly. (2) Low copy repeats in human diseases. Several human diseases are associated with deletions or duplications of specific genomic regions. Such repeat patterns can be identified by a repeat finding program. (3) Checking uniqueness of hybridization probes. This application is technological. On a microarray, sequence probes that are unique in the genome under consideration can be deposited. This uniqueness can be ensured with a repeat finder. (4) Comparative genomics. Concatenating two different genomes and looking for repeats with varying rates of divergence allows for comparing the two genomes on different grades of similarity.

3.6 Analyzing Genome Rearrangements

With the availability of a growing number of genomes, comparison of different genomes becomes an even more valuable source of insight into the evolutionary development of species. It turns out that nature rearranges genomes in intricate ways to form new genomes. The indivisible operations that nature uses for rearranging genomes are translocation, that is, integrating some sequence fragment at another location in the same or a different chromosome, reversal, that is, translocation and integration into the oppositely directed DNA strand, as well as fusion and fission of chromosomes. We are concerned here with rearrangement events on the species level, not those on the level of the individual (which are mutation and recombination).

The comparison of two genomes from different species aims at exhibiting which parts of the genome 1 correspond to which parts in genome 2 and thereby reveal the respective sequence of rearrangement operations. Of course, we have to deal with mutations that distinguish the two sequences at the same time. In general, this is a sequence analysis problem similar to sequence alignment, in spirit, but with the rearrangement operations as basic operations instead of mutation and gap insertion. We can attribute a cost to each operation, as we did in sequence alignment, and optimize the cost of the sequence of operations transforming one genome sequence into the other. Algorithmically, the problem is more complex than that of sequence alignment ([60] Chapter 10, [61]). A basic ingredient of the algorithms is the breakpoint graph, which represents the available options for a rearrangement.

The problem becomes even more difficult if several genomes are to be compared and we are looking for a phylogeny [62]. These algorithmic developments still make several biologically unjustifiable assumptions. For instance, recent comparative investigations of the genomes of human and mouse have revealed that rearrangements of genomes happen at different scales. Intrachromosomal micro-rearrangements affect sequence segments less than 1 Mb in length; macro-rearrangements affect much longer sequence segments and can happen inside a chromosome as well as between chromosomes. Recently, the algorithmic

technology has been adapted to this finding [63].

Computational analysis of genome rearrangements is just on the verge of transcending a basic algorithmic investigation to generating useful insight into the evolution of species genomes [64, 65] and the relationship between genome rearrangement and disease [66].

4 Molecular Structure Prediction

In many cases, the 3D structure of a molecule can provide essential clues to its molecular function. This is the case especially for proteins and RNA that exercise their functional role by binding to other molecules in a unique and predictable fashion. This happens especially for enzymes and molecules that are involved in regulation and information transfer within the cell or between cells. While DNA has a very uniform double-helical structure, RNA and proteins can fold in a large variety of structures. These molecules are stable in the sense that they retain their overall fold, yet they can vary their structure in subtle ways. Examples of this phenomenon are domain movements of allosteric proteins or the phenomenon of induced fit, by which the surface of the binding site of a protein changes subtly to accommodate its binding partner.

The close relationship between molecular structure and molecular function gives the structure prediction problem its great relevance. Today, we cannot reliably predict the structures of proteins or RNA, in general. However, the protein structure prediction field is in a more advanced state than RNA structure prediction. We will discuss both fields, in turn.

4.1 Protein Structure Prediction

The protein structure prediction problem has often been called a *Grand Challenge* problem in computational biology. It has received wide attention in the scientific community and even in the media. Computer manufacturers have used it as one of the main motivators for their high-performance computer developments. The reason for this popularity is probably that the problem is quite easily communicated, while a solution still evades us to this day. Here, we discuss three versions of the problem that have received wide scientific attention. All versions take the protein sequence as primary input. Some of the methods use additional input, such as the evolutionary neighborhood of the query protein or a database of known protein structures.

There are a large number of structure prediction methods available on the Internet, today. The community also provides sophisticated means of constantly evaluating these methods. Every two years the CASP contest (critical assessment of structure prediction methods [67]) stages an international experiment for predicting protein structures that are unknown at the time of prediction but are resolved by the time of evaluation of the predictions. Furthermore, there are servers on the Internet that continually assess and compare the performance of protein structure prediction methods [68, 69].

4.1.1 Secondary Structure Prediction of Proteins

The secondary structure prediction problem aims at deciding, for each residue in the protein sequence, whether it is located in an α-helix (H), a β-strand (E), or neither (C). We call the latter regions *coil*

regions. There are variants of the problem that distinguish different helices (α-helix, 3_{10}-helix, etc.) and subdivide coil regions further, for example, by introducing different turns. Here, we will not discuss these variants.

In modern methods, the first step is to scan through a protein sequence database, retrieve homologs of the query protein, and compute a multiple alignment of all retrieved proteins. This provides critical additional input to the structure prediction procedure: For each sequence position, we now have not just a single residue but a profile of residues that related proteins provide. The introduction of this critical information was the key ingredient of boosting the structure prediction accuracy above 70% in the early nineties [70]. Given this information, a variety of classification methods can be used to predict the residues states H,E,C; among them, neural nets [70, 71] are the most popular variant. Additional improvement on the structure prediction accuracy can be obtained by running several methods and forming a consensus between them [72–74]. Such methods achieve an accuracy of just under 80%. The ends of secondary structure elements tend to be predicted more unreliably than their central regions. For the profile to be unbiased, the sequence database from which we draw the profile has to be unbiased in the sense that there are no protein families that are over- or underrepresented in the database.

The accuracy of secondary structure prediction methods is assessed by comparing their prediction to secondary structure assignments that are automatically derived from resolved 3-D protein structures. Different methods for this purpose, such as DSSP [75] and STRIDE [76] differ in their assignments. Owing to these differences, one cannot expect the prediction accuracy to increase much above 90%.

4.1.2 Similarity-based Protein Structure Prediction

The most successful approach to the prediction of 3D protein structure takes a database of resolved protein structures, the so-called template structures as secondary input. Rather than assembling the protein structure of the sequence from scratch, we repeatedly ask the question whether the protein structure attains any of the template structures. We only collect reasonably different structures in the template database – one convention is to require the sequence of any two template structures to have at most 40% sequence identity. This results in a database with roughly 5700 structures today.

How do we decide how likely it is for the sequence of the query protein to attain a given template structure? We perform a pairwise alignment of the query sequence with the sequence of the template structure. Here we use a position-specific amino acid substitution matrix (PSSM) that represents the structural preferences for a residue on the query sequence to be located at the location of the matched residue in the template structure [31, 32]. As in secondary structure prediction, we can enhance this approach by introducing information from evolutionarily related proteins in the form of a sequence profile on the side of the query sequence as well as the template sequence plus additional information, for example, stemming from secondary structure predictions [77].

This kind of aligning of the query sequence with the sequence of a template structure is called *protein threading* [78]. The score of the alignment tells us the level of preference for the query sequence to attain the template structure. Ideally, the

template that can be aligned to the query sequence with the highest alignment score should provide the structural model for the query protein. However, since alignment scores reflect structural preference only inadequately, this model selection procedure is fallible. Thus, the score has to be accompanied with a confidence value that rates how much we can believe in the prediction. Often, confidence scores are based on statistical significance, which rates how unlikely it is to obtain the alignment by chance. But other, more heuristic choices of confidence values have proven effective as well [79].

The improvement of the quality of protein structure prediction rests mainly on the improvement of the scoring function. There are two ways to improve the scoring function. The first is to find ever more suitable functional forms for scoring. In scoring, one has to make a tradeoff between the number of terms to include into the function and the computational efforts for scoring. Interaction terms between a growing number of partners within the protein afford more accurate scoring (if the interaction terms are correct) but also take more time to compute. The second is, given a fixed functional form to improve the scoring parameters. These parameters are typically fitted to existing protein structures. Thus, with the growing number of protein structures available, these parameters can be refitted regularly and should automatically lead to better scoring functions, given that the functional form for scoring is suitable.

The performance of protein threading methods is typically assessed by *fold recognition* benchmarks [68, 69]. Here the object is to retrieve the template structure that is most similar to the structure of the query protein. The performance can be quantified in terms of the number of correctly assigned folds or, in a more detailed fashion, by rating the quality of the alignment, on which the fold assignment is based. The accuracy of protein threading methods depends greatly on the similarity between the query sequence and the template protein. It is low in the case of low sequence similarity and high in the case of high sequence similarity. Over the whole protein structure database, we can achieve an accuracy of above 70% correctly assigned folds today.

Aligning the query sequence to a template protein is only the first step of producing a full-atom protein structure model for the query protein. While it is a critical step for the similarity range of below about 40% between query and template sequence, it is a trivial exercise in high similarity ranges above, say, 70%. A faulty alignment leads invariably to a wrong protein model.

The alignment only provides the structure of part of the backbone of the protein. Gaps in the alignment represent parts of the query sequence that we cannot map onto the template structure (if gaps occur in the template sequence) or tears and rips in the backbone model of the query sequence (if gaps occurs in the query sequence). The former gaps mostly stem from loops in the query protein that have no counterpart in the template structure. These loops have to be modeled in a separate loop-modeling step. Modeling loops can be achieved by taking loop templates from a database of structures of protein fragments, or by using energy optimization methods. Rips in the backbone of the query protein have to be mended and finally the side chains of the query protein have to be attached to the backbone. Here, the variants are to use a database of side-chain rotamers or to do energy optimization.

Similarity-based protein modeling tools combine these different steps in different ways and using different algorithmic procedures such as discrete optimization, nonlinear optimization, and constraint programming [80–82].

While similarity-based modeling is quite successful today, it has to be mentioned that this approach cannot discover yet unseen protein structures. Rather, it can only rediscover structures that have been seen before as attained by different protein sequences. As we can only assume to have uncovered about a third of all protein structures used by nature [83], this approach has strong limitations.

Therefore, homology-based modeling has been combined with experimental procedures for protein structure prediction in *Structural Genomics* initiatives [84]. The basic idea is that with bioinformatics methods, one first selects a set of yet structurally unresolved protein sequences that (1) are likely to fold into a yet unseen structure and (2) are likely to submit to the experimental technique for the structure elucidation that is to be used, that is, the protein should crystallize, if X-ray diffraction is to be used for structure determination [85, 86]. The selected proteins are then submitted to experimental structure elucidation. For this purpose, high-throughput versions of experimental structure determination methods have to be developed. Any newly discovered protein structure can then provide a new template for homology-based structure prediction to further expand the space of protein structure models. With the most ambitious structural genomics initiatives, the goal is no less than to cover all (or as much as possible) of protein structure space. The throughput of experimental structure prediction methods is not yet large enough to consider high-throughput structure determination a reality today [87].

4.1.3 *De Novo* Protein Structure Prediction

De novo structure prediction does not use structural templates but attempts to construct the protein structure from the sequence from scratch. This affords not only the rediscovery of known template folds attained by new protein sequences but the actual discovery of new (never seen) folds. Currently, there are basically two approaches to this problem. One uses energy minimization. This approach is of quite limited effect. The only reports have been on being able to model short stretches (a few dozen residues) in small proteins. In the late nineties, David Baker and his group invented a second approach that takes up the idea of modeling the protein structure from structural templates of small protein fragments (nonapeptides) that are taken from resolved protein structures [88, 89]. This assembly procedure is equipped with an effective scoring function [90]. This ROSETTA procedure has given the field a major push and provided significant progress in recent CASP events [91].

The ROSETTA method has also been applied to improve secondary structure prediction [92].

4.2 RNA Secondary Structure

In principle, the aspects of RNA structure prediction are similar to those encountered with proteins. However, the state of RNA structure prediction is not as mature as that of protein structure prediction. There are two aspects in which RNA structure prediction differs from protein structure prediction. The first is that the secondary structure patterns of RNA are different

from those of proteins. Whereas we have α-helices and β-strands in proteins, RNA secondary structure is made up of double-helical base pairing patterns within the RNA sequence. Thus, the secondary structure prediction problem for RNA differs from that of proteins. The second is that 3D structure prediction

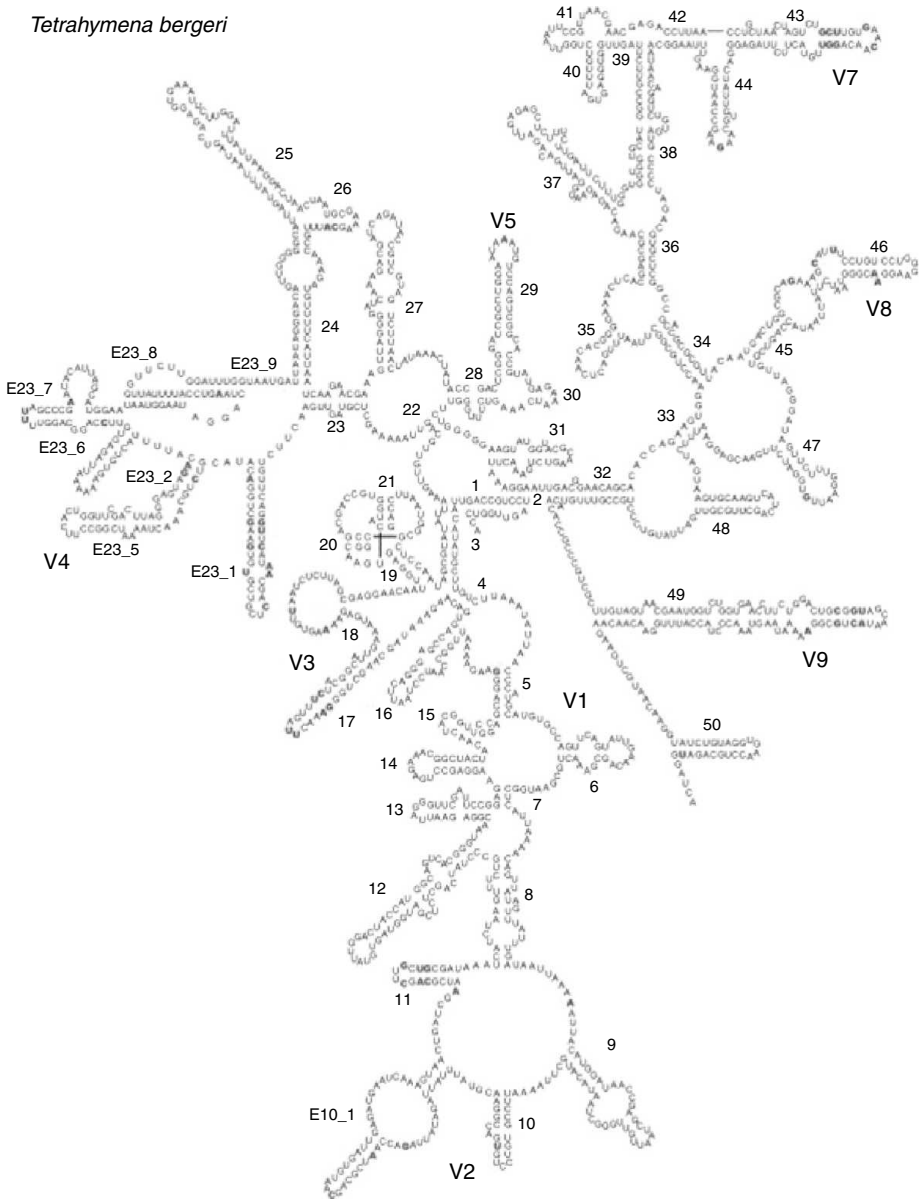

Fig. 5 Secondary structure of the RNA from the small ribosomal subunit of *Tetrahymena bergeri*. The long lines denote pseudoknots.

of RNA is hampered by a lack of data for resolved RNA structures, as compared to proteins. We have over 20 000 protein structures available today, but only a few hundred RNA structures (see http://www.rnabase.org/).

An intensively studied problem on the way to RNA 3D structure is the RNA secondary structure prediction problem. RNA exhibits secondary structure due to the base pairing occurring within the molecule. The usual Watson–Crick base pairs (A–U, C–G) occur with preference, but other pairings (U···G, A···G) and even (U···U) are also seen. Figure 5 shows a typical RNA secondary structure and indicates that RNA secondary structure basically has a tree shape, if one disregards the usually few base pairings violating this shape. (These base pairings are called *pseudoknots* [93, 94], see Fig. 5.)

There are basically two approaches to RNA secondary structure prediction. The first is called *comparative sequence analysis* and deduces the likely location of base pairings from correlated mutations in the respective positions along multiple alignments of homologous RNA sequences. Traditionally, the process was mostly performed by hand, but recently algorithmic versions of this scheme have been presented [95–97]. The second approach is energy-based. An additive energy model is assumed in which each local structural feature, such as a stacked base pair and each of the various bulges and loops in the secondary structure (*see* Fig. 5), is attributed a certain energetic contribution. These energetic values are deduced from experiments and simple model assumptions. Then, a combinatorial optimization algorithm searches for the RNA secondary structure with lowest energy. The optimization can be done efficiently using dynamic programming, if we assume that the RNA structure is treelike as described above. This method has been pioneered by Zuker and Stiegler [98], and it is quite popular, since it lends itself to many generalizations. One can select different tradeoffs between the complexity of the energy model and the runtime of the minimization algorithm [99]. One can compute not only the optimal but also a set of near-optimal foldings and display them together in a so-called *energy dot plot* in order to identify the putatively most stable regions of the structure [100]. Finally, since the energy contributions from local structure elements can be chosen to be temperature-dependent, one can assemble a ''movie'' of the energetically most favorable RNA structures as the temperature rises (or falls). Also, thermodynamic quantities such as the heat capacity can be computed [101] with the same efficient dynamic programming approach. All of these methods disregard pseudoknots; however, these have to be factored in by special algorithms that make the computation more expensive [102, 103].

5 Analysis of Molecular Interactions

The analysis of molecular interactions is a major component of understanding protein function as well as a basic technology for searching for new drugs. By *interaction* we mean noncovalent (only in rare cases does one have to consider the formation of covalent bonds) binding of two or more molecules. Here, we only discuss interactions between two molecules. We distinguish large molecules (macromolecules, such as proteins, DNA or RNA) and small molecules (such as metabolites or drugs). Here, we will mainly discuss the case in which the

macromolecule is a protein. Accordingly, we consider the protein–protein docking problem, which considers the formation of a complex between two proteins, and the protein–ligand docking problem, which analyzes the complex of a (small-molecule) ligand binding to a protein. Both problems are surprisingly different, in terms of their relevance and their bioinformatics solution.

5.1 Protein–Ligand Docking and Drug Screening

All docking problems are vehicles for understanding molecular interactions from a basic research point of view. In addition, the protein–ligand docking problem is of central interest mainly because of its application in drug design. This is why protein–ligand docking receives much more attention from pharmaceutical industry than the protein–protein docking problem. This application also places important requirements on protein–ligand docking software. Specifically, the demand is on high throughput: In order to screen large databases of putative drug molecules, each instance of the protein–ligand docking problem has to be solved in as short a time as possible. Today, the relevant compute times for drug screening by docking are in the second-to-minute range for docking programs that analyze full ligand and restricted protein flexibility. The ligand is generally assumed to be druglike, with molecular weights up to about 500 Da and up to a dozen rotatable bonds. Peptides, which can be larger and have more rotatable bonds, exercise the limits of general protein–ligand docking software and require special approaches.

Two main issues have to be accounted for in a docking program. One is to find the geometric fit between the two interacting molecules. This entails finding the right conformation of the – generally highly flexible – ligand and the protein (involving the analysis of induced-fit conformational changes in the protein if the software allows for it). In general, a docking program will generate several putative protein–ligand complexes that are feasible geometrically. Therefore, we need a second selector in order to distinguish the correct binding mode(s) from wrong ones. This selector is an estimate of the differential free energy of binding between the complexed and the uncomplexed molecules. According to the laws of thermodynamics, we are looking for the conformational state that minimizes this figure. In addition, the energy score can be used to distinguish good from bad lead compounds; the lower the energy score, the stronger the binding affinity of the ligand to the protein and more interesting the ligand is as a putative lead compound. Therefore, energy scoring is at the heart of docking. Unfortunately, energy scoring is also the least well-understood part of docking. In addition, in order to abide by the strict time constraints, generally reduced energy models have to be used that result in inaccurate energy estimates. Figure 6 exemplifies the result of docking a small-molecule ligand into a protein.

There are a handful of widely used docking programs (e.g. DOCK [104], GOLD [105], FlexX [106], Fred (OpenEye Software), AutoDock [107], LigandFit (Accelrys), ICM [108]) that use a few successful approaches to subproblems of protein–ligand docking in different combinations. Several recent reviews compare these programs [109–112]. For handling ligand flexibility, some programs precompute a limited set of rigid conformers that are docked into the

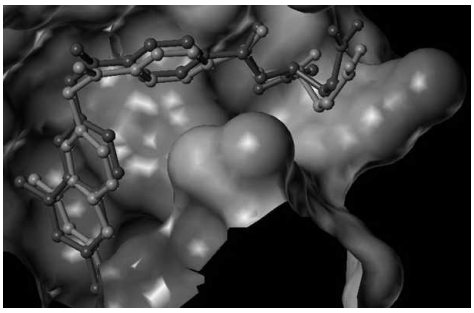

Fig. 6 Docking of the drug methotrexate into the active site of the protein dihydrofolate reductase. Green: observed crystal structure. Red: docking Result computed by the docking program FlexX.

binding site of the protein one after the other. Other programs incrementally build up the ligand inside the binding pocket of the protein out of more or less rigid fragments. Again, others use more generic conformational sampling schemes based on genetic algorithms, Monte Carlo techniques, or molecular dynamics. For energy, scoring force fields that are based on pair potentials are used as well as more rudimentary and therefore faster *empirical* scoring functions that only score additive contributions of short-range interactions between the protein and the ligand [113–115]. Among the pair potentials, the more classical force fields are derived from physical principles [116, 117], newer ones are based on an abstract functional form and fitted to the data of existing protein–ligand complexes. The latter class of scoring functions is generally called *knowledge-based* scoring functions [118, 119]. Improving scoring functions is the bottleneck for protein–ligand docking.

Docking programs that build up the ligand inside the binding pocket of the protein lend themselves to more efficient screening procedures on combinatorial ligand libraries. Here, the alternatives of the so-called R-groups in the ligand scaffold can be tried out during the buildup procedure. This can increase the screening throughput significantly [120, 121].

As an aside, it shall be noted that there is a substantial spectrum of methods for drug screening in case that the structure of the protein is not available. In this case, the query for the search through ligand databases is not the protein but a compound that is known to bind to the binding pocket of the protein. The search looks for compounds that are similar to the query compound. The notion of molecular similarity is critical here. It is usually based on one or a set of molecular descriptors, that is, abstractions of the molecule that entail information about relevant molecular properties. Different kinds of descriptors are in use. Popular descriptors consist of binary vectors that list (sometimes up to a hundred thousand) molecular properties and code, for each property, whether the molecule has that property or not. In this case, molecular similarity analysis is reduced to a comparison of binary vectors, which can be done very quickly. Thus, the resulting screening procedures have a throughput of several ten thousand molecules per second [122]. More complex descriptors involve a topological analysis of the molecule. Such descriptors incur more complex similarity analysis algorithms that only have a throughput of about 100 molecules per second. However, with such descriptors, the conformational

flexibility of ligands can be handled [123]. Overviews of approaches to drug screening by molecular similarity can be found in [124–126]

These initial drug-screening procedures only look for *lead compounds* that are (more or less) tightly binding to the protein. In order to convert a lead compound into a drug, its so-called *ADMET* properties have to be optimized. Here A stands for absorption (by the intestinal barrier, if given orally), D for distribution (throughout the body, involving deliverance to the location where the drug is supposed to act), M for metabolism (the tendency of drug to be metabolized before it reaches its place of action), E for excretion (of the drug from the body) and T for toxicity. Computational procedures for assessing these properties are summarized in [127, 128]

5.2 Protein–protein Docking

Protein–protein docking is central to understanding regulatory events in living systems. Therefore, the protein–protein docking problem is a vehicle in understanding the inner workings of cells and the molecular basis of diseases. Since proteins are not preferred drugs, these days, the protein–protein docking problem cannot help in finding new drugs, though it can be an aspect of finding target proteins – for instance, when the binding of two proteins is supposed to be inhibited by a drug. The screening aspect is not as important for the protein–protein docking problem as for the protein–ligand-docking problem. One could think of docking a protein against all structurally resolved or modeled proteins of an organism, but the number of resulting instances is still orders of magnitude smaller than for drug screens.

In protein–protein docking, the notion of molecular surface is more prominent than in protein–ligand docking, because both binding partners are basically rigid – aside from the events of induced fit occurring along the contact surface. These events need to be considered. Not considering protein flexibility incurs higher penalties in protein–protein docking than in protein–ligand docking. The energetic differences between the bound and unbound complex are usually higher for drugs (that are supposed to stick to the protein) than for proteins (that are supposed to disassociate again). All this makes protein–protein docking an exceptionally hard variant of the docking problem.

Approaches to protein–protein docking usually build on a procedure for rigid docking and incorporate induced fit on top of this algorithmic basis. Methods based on Fourier analysis or Fourier transform [129], geometric matching [130], and genetic algorithms [131] are approaches for the rigid-docking part. The induced fit can be incorporated rudimentarily by "softening" the protein surface using appropriate energy potentials or explicitly by sampling different side-chain conformations. In general, the energy-scoring problem is the same for protein–protein docking as for protein–ligand docking. If a rudimentary scoring function is used, the ranking of the different complexes that are generated by the docking program by energy is inaccurate, and rescoring of the high-ranking complexes with a more accurate scoring function may be necessary. Explicit sampling of side-chain conformations can be done by a combinatorial search procedure [132] or with genetic algorithms [133]. The dead-end elimination

algorithm is an effective method for reducing the number of conformers to be searched [134, 135].

State-of-the-art protein–protein docking procedures are ICM-DISCO [136], 3D-DOCK [137, 138], and ZDOCK/RDOCK [139, 140]. These programs and others took part in the CAPRI protein–protein docking contest (Critical Assessment of Prediction of Interactions http://capri.ebi.ac.uk/ [141]) that was started in 2001 [136, 142, 143]; the contest is going into its fifth round now. Reviews of protein–protein docking can be found in [144–146].

5.3 Other Molecular Docking Problems

Protein–DNA docking is important in understanding regulatory events in the cell. Because of the high regularity of the DNA double-helix structure, the usually large structural changes in the protein and the importance of the solvent in protein–DNA binding, this version of the docking problem is an especially difficult variant of the protein–protein docking problem. A few attempts have been made to adapt existing protein–protein docking software to protein–DNA docking [146] or to develop methods specially tailored to this problem [147, 148].

The other variants of the docking problem (protein-RNA, DNA-ligand, RNA-ligand) are covered even less in the literature.

6 Molecular Networks

While the interactions of pairs of molecules are essential basic components of cellular function, the inner workings of a cell only become apparent at the level of complex networks of such interactions. Therefore, the modeling and analysis of biochemical networks is a major aspect of understanding the cell, as a whole, a goal that has been formulated by the newly appearing field of systems biology [149].

Biochemical networks in cells are very complex. Therefore, their study is usually confined to restricted contexts. The classification that will guide the structure of this section is divided into metabolic networks and regulatory networks. Both subclasses of networks have their specially targeted databases and a growing set of analysis procedures. A more general view of protein interaction networks is afforded by cell-wide protein interaction screening experiments. This topic is taken up in Sect. 8.3.

6.1 Metabolic Networks

The metabolic network of a cell summarizes the set of reactions inside the cell that metabolize small molecules (called the *metabolites*) with the help of catalytic proteins (called *enzymes*). Coherent sequences of successive reactions are called *pathways*; if a pathway closes in on itself, it is called a *metabolic cycle*. The object of a pathway or a cycle can be to synthesize or degrade a macromolecule or a metabolite or to convert or release usable energy. Metabolic networks are very uniform. They are composed of elements as shown in Fig. 7, with two vertices called the *educt* and the *product*, an edge signifying the reaction labeled with the catalyzing enzyme, and possibly attached cofactors. Reactions can be reversible or irreversible, the latter case being denoted by a pointed arrow in the unique direction of the reaction. The composition of such elements at the metabolite nodes

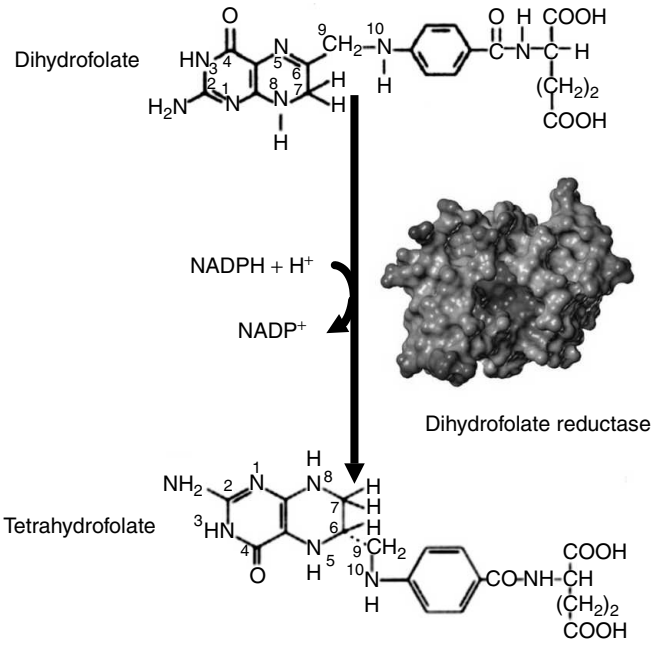

Fig. 7 A metabolic reaction. Educt: dihydrofolate. Product: tetrahydrofolate. Enzyme: dihydrofolate reductase (DHFR). This is the reaction blocked by the inhibitor bound to DHFR in Fig. 6.

yields complex networks such as shown in Fig. 8.

The regular nature of metabolic networks affords the opportunity to build large uniform databases and to devise systematic analysis procedures of these networks. In order to completely describe a single reaction such as the one in Fig. 7, we have to supply the kinetics of the reaction, that is, the concentration gradients of the involved molecular partners in terms of their starting concentrations. While the form of many reactions is known today, the reaction kinetics is a sorely missing piece of data for most reactions.

Metabolic network databases include organism-specific databases such as EcoCyc [150] (for *E. coli*), HinCyc [151] (for *H. influenzae*), PseudoCyc [152] (for *P. aeruginosa*) (Other computationally derived metabolic databases are available at the BioCyc website (http://biocyc.org)) and databases spanning several organisms ranging even over different kingdoms of life, such as KEGG [153], MPW [154] and MetaCyc [155]. For these databases, the basic unit of description is the metabolic pathway. The databases provide data records and images describing such pathways. In recent times, the images have become increasingly processable by computer. Then there are databases that concentrate on the single reaction, such as BRENDA [156] ENZYME [157], and the new integrated effort IntEnz [158]. All metabolic databases are equipped with their own set of tools for querying the databases, for navigation and for visualization of the search results.

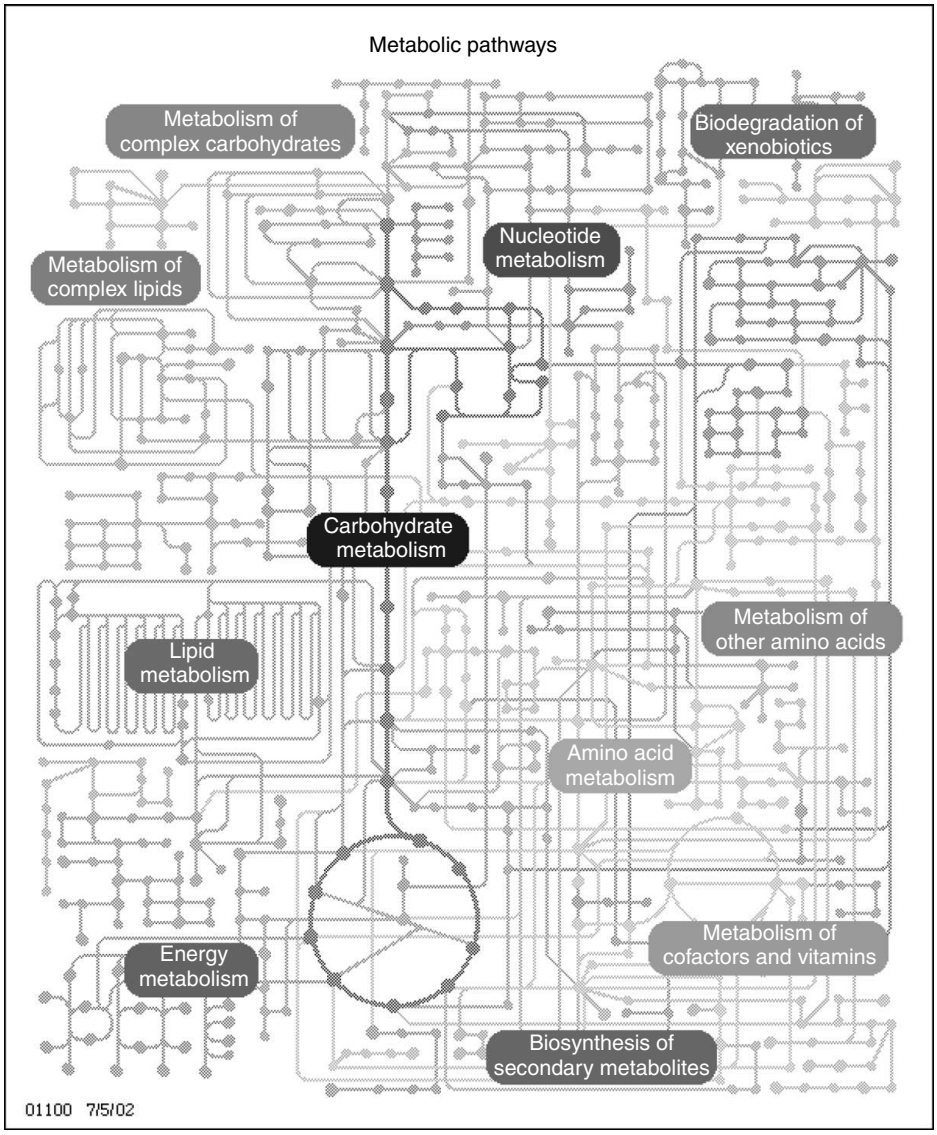

Fig. 8 Schematic diagram of part of the metabolic network of *E. coli* (from http://www.genome.ad.jp/kegg/pathway/map/map01100.html)

These databases are comprehensive enough to enable comparisons of the factual or putative topology of metabolic pathways in different species with fully sequenced genomes. Such comparisons have been undertaken for several metabolic pathways [159], partly involving genomic context methods for protein function prediction (*see* Sect. 8.4). Furthermore, mathematical methods have been developed to analyze the topological structure of pathways. The so-called flux balance analysis

method uses linear optimization to assign flux values to the edges of a metabolic network that maximize some objective function, such as growth per substrate uptake, under steady state conditions [160]. In contrast, metabolic flux analysis decomposes pathways into the so-called elementary flux modes [161, 162]. The elementary flux modes are the minimal components of a pathway that can act coherently and independently under steady state conditions. Both types of analysis aim at yielding insight into the biological structure of a metabolic network from its topology. There is software to perform this analysis on medium-sized pathways [163]. Of course, the steady state is a special case for a cell. If we drop it, we have to resort to more general analysis methods based on ordinary differential equations that model the reaction kinetics in the pathway under consideration. There has been extensive software development for this purpose [164–167]. However, the data are missing in many situations. Large metabolite screening projects aim at removing this deficit [168–170].

6.2 Regulatory Networks

The regulatory network is generally thought of as being the part of the biochemical network inside the cell that facilitates information and communication, rather than turning around matter. Signal transduction pathways and protein interaction networks that facilitate transcription of genes are two essential parts of the regulatory network. The regulatory network is much more difficult to approach than the metabolic network. One reason is that it is more inhomogeneous. In a regulatory context, there are many ways in which a molecule can affect another that is of importance, for example, agonistic, antagonistic, activating, deactivating, inhibitory and so on. Thus, currently, there is not even a generally accepted notation for representing regulatory relationships. Furthermore, the few databases of regulatory networks are more cursory than the well-developed metabolic databases. Where metabolic databases contain up to well over a hundred thousand genes, regulatory databases have grown to a few thousand genes. Most of the knowledge on regulatory pathways is still buried in the literature, that is, it is not in computer-digestible form. However, the amount of knowledge existing in the literature is so large that several attempts are being made at systematically mining the literature with automated methods to extract that knowledge. Of course, owing to unsystematic notation and difficulties in parsing text generated by humans, such efforts generated many false positives and the resulting data are therefore to be taken with the greatest caution (see also Sect. 8.6).

TRANSPATH [171] is a prominent database of signal transduction pathways. The database web interface includes tools for querying and visualization as well as an integrated tool for the analysis of microarray data in the context of the regulatory networks (*see* Sect. 7). The protein interaction databases DIP [172] and BIND [173] also describe molecules in terms of pathways and provide reaction maps.

There are basically two ways of analyzing regulatory networks. One is to simulate and analyze established networks. A straightforward approach here is to model regulatory relationships with the same framework of differential equations that is used for the nonstationary analysis of metabolic networks. This approach is general and can be accurate, given sufficient data, but it may incur performance

problems and lack the model hierarchy that biologists usually attribute to biochemical networks. The signal pathway database DOQCS [174] provides a repository of models of signal pathways on this basis. Qualitative simulation methods simplify the general differential equations model to simpler function forms [175] or even to discrete models [176]. The other, much more challenging, question is how to uncover yet unknown regulatory relationships and pathways from experimental data. One set of data from which one hopes to be able to do so is expression data (Sect. 7).

6.3 The Virtual Cell

The ultimate goal of systems biology is to provide a computational simulation of the whole cell. The *E-Cell Project* is undertaking a comprehensive effort toward this goal encompassing the computational work to provide the simulator [177, 178] and being embedded into a large metabolite screening project that is supposed to generate the necessary data for the simulation [179]. *Genomic Object Net* is another virtual cell project that is based on combinations of discrete and continuous simulation mechanisms [180].

7 Analysis of Expression Data

In the early 1990s, the first steps of developments were undertaken toward measuring the profile of genes transcribed in a cell in a certain cell state. This information goes way beyond the information contained in the genome sequence, since it can help distinguish between different tissues and different cell states within the same tissue (e.g. healthy/diseased). Thus, it was hoped to be the basis for entirely new approaches towards diagnostics and therapy of diseases. Technically, the most convenient way of measuring gene expression profiles is on the basis of the transcribed mRNA, rather than protein. The reason is the much more uniform molecular form of DNA that lends itself more conveniently to laboratory procedures than proteins. There is a tradeoff in choosing mRNA as the level on which gene expression is to be measured. On the one hand, mRNA expression levels do not always correlate well with protein expression levels, which are governed by regulation of protein translation and degradation, in addition to transcription regulation. Also, posttranslational modifications of proteins, which have an essential effect on protein function, cannot be measured on the mRNA level. Still, because of the technical accessibility, mRNA expression measurement became very popular, first on the basis of ESTs (expressed sequence tags) and currently mainly on the level of cDNA microarrays.

The advent of cDNA microarrays in the late 1990s has created a large surge of statistics and bioinformatics activities targeted both to configuring the arrays and to interpreting the resulting data. Today, not only the potential but also the limits of microarray measurements are becoming apparent. Thus, many of the hopes of making protein function accessible directly through microarray measurements have not materialized. But it is becoming clear that diagnostic procedures progress significantly through expression measurements and in concert with other biological data, expression measurements can help gain some insight into the biological role of genes and proteins.

7.1 The cDNA Microarray

Without going into the details of the technology, we give a quick summary of the essentials of the cDNA microarray here, in so far, as it is relevant to bioinformatics. The expression profile measurement begins with extracting all mRNA from a homogeneous cell lysate. The mRNA is then back-translated to cDNA and labeled radioactively or fluorescently for detection. The cDNA is then run over a microarray. On the microarray, an arrangement of complementary sequence probes for relevant genes is arrayed. The length of the probes differs in different technologies from 25 mers across about 70 mers to full-length genes. The cDNA hybridizes to the respective probes and a detection device measures the quantity of hybridized cDNA. The detected signal levels provide the raw data for analysis and interpretation.

Today, cDNA microarrays can have many thousand probes on them and collect all genes for small organisms or many putative genes for diseases in complex organisms (heart chip, cancer chip, etc.). There are basically two classes of arrays: one-channel arrays and two-channel arrays. One-channel arrays are the ones described above [181]. Two-channel arrays allow for hybridizing cDNA from two different cell lysates, each colored differently, say, red and green, in the same experiment [182]. Thus, we achieve a differential profile of two cell states with a single experiment. Several companies have proprietary microarray technologies (for an overview see http://www.bio.davidson.edu/Biology/GCAT/GSI/Microarrays.html). The Pat Brown Lab at Stanford University has provided a free protocol for making two-channel arrays that is widely used today (http://cmgm.stanford.edu/pbrown/)

7.2 Configuration of Experiments and Low-level Analysis

The configuration of microarray experiments is a nontrivial technical issue that had been taken too lightly in the early days of the technology. Today, the importance and difficulty of the consistent preparation of a microarray experiment has gained widespread attention [183]. This includes rigorous quality control of the purified RNA populations, the appropriate selection, and configuration of the probes on the chip to reliably select the desired cDNAs and avoid inadequate or nonspecific hybridization [184], a sufficient number of replications of the experiment [185], and a sufficient logging of the experiment. For the latter purpose, the MIAME standard (minimum information about a microarray experiment) has been developed [186]. The public repository of expression data ArrayExpress, which follows this standard, is in existence and growing in volume [187]. The National Center for Computational Biology (NCBI) is providing another database of expression data, the Gene Expression Omnibus (GEO) [188].

The configuration of a microarray experiment is closely related to the low-level analysis of the data generated by the experiment [189, 190]. By this we mean the procedure that turns the raw readouts of the experiment into a number signifying expression level, say, in terms of RNA copies per cell, or in terms of fold changes based on some reference profile. Low-level analysis has to incorporate and appropriately model the variances in

expression levels stemming from technological and biological sources of error. The respective statistical procedure is called *normalization* of expression data. Quite a few methods for normalizing expression data have been published, and the choice of the appropriate method is a central aspect of low-level analysis. Overviews of basic normalization methods are given in [191, 192], newer methods can be found in [193, 194].

The result of low-level analysis is an *expression data matrix* of normalized expression levels. This matrix has the dimensions number of probes × number of samples. Here the number of probes (genes) is usually very large, in the several ten thousands. The number of samples (experiments) is quite low, at most in the dozens. Thus, the expression data matrix is quite unbalanced. This has strong ramifications for the analysis of expression data.

The final step in low-level analysis is to decide what a differentially expressed gene is. To this end, we have to fix a threshold value of change in expression level, above which we regard a gene as being ''conspicuous.'' This is a statistical question that has to be resolved in terms of a model of background variation specific to the gene and the experiment.

7.3 Classification of Samples

The considerably easier problem is to classify the (few) samples on the basis of the expression levels of the (many) probes. The related application problem is a diagnostic one: to distinguish different types or stages of a disease based on the related expression data. This problem is of high clinical relevance and has been investigated as soon as the microarray technology became available. An especially widely studied type of disease in this context is cancer. One of the first studies on classifying microarray samples targeted two types of leukemia (acute myeloid leukemia, AML and acute lymphoblastic leukemia, ALL) that are hard to distinguish histologically [195]. Since then, many studies on different types of cancer followed.

For classifying samples, a variety of statistical learning techniques can be used. Supervised learning techniques use labeled data – in this case, samples that are known to originate from patients that have contracted a certain type of the disease. Then a statistical classifier is generated that classifies future samples. Learning methods include decision trees, neural nets, support vector machines, and others [196, 197]. Depending on the types of disease to be distinguished, high classification accuracy can be achieved, sometimes over 90%. This means that the type of disease can be determined quite reliably on the basis of mRNA expression data. This has been substantiated quite impressively on a wide variety of cancers [198]. An important part of supervised learning is feature selection, that is, the identification of small sets of genes whose expression levels are indicative of the type of disease. Often, one can identify a few dozen genes whose expression levels can determine the disease type with almost the same accuracy as the classifier operating on the expression levels of all genes. Genes selected in this way can also be candidates for primary actors in the disease process. Feature selection is a more general way of determining genes that are relevant to a disease than detecting differentially expressed genes, since it takes sets of genes into account instead of just single genes.

In contrast to the supervised learning techniques, unsupervised learning techniques cluster the samples into groups that may reproduce known disease types or uncover new ones [199].

7.4 Classification of Probes

Elucidating the role of genes in the disease process using expression data is much more difficult and even hopeless, in many cases. The reason is again the shape of the expression data matrix. Now, we have to learn about the differences between a large number of genes based on very few experiments – a very difficult situation. Nevertheless, there have been various approaches in this direction.

Again, people tried clustering the genes first. The rationale was that coexpressed genes might be in functional association. It became apparent soon that such a procedure is quite inaccurate [200]. Therefore, quickly the idea came up to analyze expression data together with the upstream regulatory regions of the genes. After all, it is these regions that determine transcriptional regulation. The rationale now was that coexpressed genes that share functional sites in their upstream regulatory regions should be under the same or a similar regulatory regime and therefore share a functional relationship [201–205]. Recently, this idea has been extended to include an explicit model of the involved regulators [206].

Upstream regulatory regions are not the only kind of information that one can use to enhance the analysis of expression data. Functional context as exhibited by membership in a common metabolic or regulatory pathway can also be exploited. By analyzing the expression levels of genes in the same pathway in concert, one can obtain a statistical model of this pathway. If this model is significant in the statistical sense, this can be an indication that the pathway plays some role in the disease process. Furthermore, genes with unknown functions can be tested against the pathway model. A significant test response can indicate a functional relationship of the gene with the pathway [207, 208]. This approach can be extended by including not only data from biochemical networks but also functional relationships witnessed in the scientific literature (*see* Sect. 8.6). Protein interaction data are another supplementary source of information (*see* Sect. 8.3). Such data have been analyzed in concert with expression data to elucidate molecular pathways [209, 210]. Here, the working hypothesis is that the protein product of genes that exhibit the same expression profile tend to interact. In all cases, the analysis methods are again statistical learning schemes. Especially, if several sources of information have to be integrated, the quite general machinery of Bayesian networks proves very effective. However, Boolean networks and other graph models are also used. The relevant statistical learning procedures can come up with regulatory networks that may be quite abstract and not closely linked to the molecular regulation process [211]. Therefore, their interpretation presents certain problems.

7.5 Beyond cDNA

As mentioned above, mRNA represents an intermediate step from the genotype (DNA) to the phenotype (post-translationally modified protein), which has been chosen for expression profiling mainly for technical reasons. As the

experimental technology progresses, arrays are being developed that measure gene expression closer to the phenotype than mRNA, and even analyze aspects of protein function. Peptide and protein arrays are one such technology. Here, the goal is to affix functional proteins on the chip and expose this chip to a certain ligand for binding, or the other way around, bind a set of ligands to the chip and expose them to a protein solution. Maintaining the original functionality of the molecules while affixing them to the chip substrate is the main challenge [212–214]. Also, carbohydrate arrays are being tested for probing protein–sugar interactions in glycosylation. Finally, tissue and cell microarrays are under development. While the experimental procedures are quite different for each type of array, we expect the bioinformatics procedures to be analogous for many array types. Thus, the bioinformatics technology that is being developed for mRNA arrays now should be extendible to other types of arrays in a comparatively straightforward fashion.

8
Protein Function Prediction

Elucidating protein function is one of the central goals in molecular biology. We know quite little about the function of many proteins. Today, we have hints on the function of at most two thirds of the proteins in an organism with a completely sequenced genome. Many of these hints are based on quite spurious evidence and, in fact, quite a few probably lead in the wrong direction. Thus, while we have many genomes on hand, understanding their biology is far off. This section summarizes the widely varying efforts of approaching protein function with a mixture of experimental and bioinformatics methods. For a recent review, *see* [215].

8.1
What is Protein Function?

Protein function is a colorful term. It can mean quite different things in different contexts. Sometimes, the localization of the protein (cytosolic, membrane-standing, extracellular etc.) has already been taken as a qualification of its function. In another context, the function of the protein is understood in terms of its binding partners and the reaction that it may catalyze. Again, in other situations, the role of the protein in a complex biological process (cell cycle, apoptosis etc.) is taken to be its function. It is clear that coming up with an appropriate ontology, that is, a structured vocabulary for talking about protein function, is the first step toward systematic analysis of this issue [216].

Here, we mention three efforts for providing ontologies for protein function. The oldest is the classification of enzymes by the Enzyme Commission (http://www.chem.qmul.ac.uk/iubmb/enzyme/) [217]. This is a hierarchical classification of enzymes according to the reactions that they catalyze. This classification only applies to enzymes. More recently, a larger variety of protein function has been covered by the MIPS Functional Catalog(http://mips.gsf.de/services/funcat) in the context of the annotation of the yeast genome [218]. The catalog has been extended to other species since then. As per the classification by the Enzyme Commission, it exhibits a hierarchical treelike structure (with up to six levels, where the EC code has four). The most extensive effort of creating an ontology for protein function is by the

international Gene Ontology Consortium (http://www.geneontology.org/) [219]. Again, the ontology is hierarchical. This time, however, we have three hierarchies in order to distinguish between the three fundamentally different approaches to protein function discussed above: cellular component, molecular function, and biological process. Also, instead of the tree hierarchy, a directed acyclic graph is used such that a child node can have different parent nodes. The ontologies are expanded continuously and function annotations of genes and proteins in databases and in the literature are linked to the ontologies. This whole body of knowledge provides an increasingly voluminous gold standard by which computational methods for protein function prediction can be evaluated. Nevertheless, the structure of current ontologies provides only a structured vocabulary and not a guideline for the functional annotation of proteins. Without such a guideline, it is difficult to express functional relationships between proteins, multiple protein function, and function variability of a protein under different physiological conditions. The GO consortium does provide a semi-formal annotation guide with its ontology (http://www.geneontology.org/GO.annotation.html). More work will have to be invested into a highly expressive and computer-digestible framework for representing protein function. As the first larger regulatory networks are being understood [220], initial efforts are being undertaken to develop the expressive tools. An example of an application in a supracellular scenario is given in [221].

8.2 Function from Sequence

Nature's prime method of conserving function is by preserving (or only slightly changing) sequence. Clearly, some parts of a protein are more relevant to its function than others. Thus, there are functionally relevant motifs in protein sequences that have to be especially conserved. There are several methods of protein function prediction that exploit these facts.

In principle, one would expect that two proteins with sequences that are very similar globally also have similar or the same function. This is not always true, however. Function is handed over from one species to another via homologous proteins, those that are closely related evolutionarily. The relationship between sequence similarity and homology is intricate and subject to much debate [222]. In particular, protein function is not always carried over between homologous proteins. We have to distinguish between orthologous and paralogous proteins, in this context. Orthologous proteins occur in different species and share a recent common ancestor. Therefore, orthologous proteins are likely to have the same function. Paralogous proteins can occur in the same species and arise by a recent gene duplication event, which also allows for function divergence. Therefore, an accurate distinction between orthology and paralogy has to incorporate phylogenetic analysis. This is a complex issue, both in the way of models and algorithms [223, 224]. Therefore, various heuristics are in use. A method that only analyzes phylogenetic relationships locally with respect to two preselected groups of proteins is implemented in the program Orthostrapper [225]. Another approach that is targeted toward whole-genome analysis does away with phylogenetic analysis altogether and reduces the notion of orthology to pure sequence similarity search. The model is that two proteins in two different genomes are orthologous if each protein retrieves the

other as the top hit in a sequence database search of the respective genome [226, 227]. This model is only a crude approximation to orthology, and therefore the resulting COGs database has to be manually curated. Another protein database that provides orthology information based on this model is SMART [228].

Orthology is a notion that applies to a pair of complete proteins. However, protein function is not only conferred to a protein, as a whole. Rather, it comes in *packets*. Short stretches of sequence, so-called *motifs* carry information on protein function. For example, the well-known ATP binding site motif, the P-loop, is characterized by a sequence fragment of length 8 respecting the motif [AG]-x(4)-G-K-[ST]. Here, the characters in brackets denote choices of amino acid residues according to the one-letter code at a single sequence position. Single letters represent unique amino acid residues (no choice), and x(4) denote a stretch of four adjacent arbitrary amino acid residues. Motifs carrying information on protein function can be found by multiply aligning protein sequences that are known to have the same function and selecting highly conserved sequence regions in the alignment. Then a motif can be derived as some kind of a consensus of these regions. The PROSITE database was the first collection of this sort [229, 230]. Initially, the motifs were mainly generated by hand. Recently, methods have been put forth to derive motifs automatically [231]. Here, the issue of sensitivity versus specificity is central: a motif that covers many of the sequences with the respective function necessarily also generates *false positives* – protein sequences that contain the motif but do not share the function. Excluding such false positives therefore means reducing coverage, that is, losing *true positives*: proteins that have the function that is to be described by the motif. However, several specific motifs (with few false positives) can together cover many true positives in the sense that each true positive contains at least one of the motifs. A database of motifs based on this idea is described in [232].

Position-specific scoring matrices or Hidden Markov models (*see also* Sects. 3.1, 3.3, 3.4, and 4.1.2) are an even more general descriptive mechanism for motifs. With them, one typically describes longer sequence fragments, such as whole protein domains. They are also easy to derive from multiple alignments. Many databases have been developed around this paradigm [233]. Most of these databases have been integrated in the domain database InterPro [234].

Finally, supervised learning methods – mostly based on neural nets – have been developed for predicting quite a few aspects of protein function including cellular localization (through the analysis of signal peptides and the prediction of transmembrane helices) and posttranslational modification features (glycosylation- and phosphorylation sites). A server offering many such methods is offered by the Center for Biological Sequence Analysis at the Technical university of Denmark, Lyngby (http://www.cbs.dtu.dk/services/). One of the methods called *ProtFun* makes a comprehensive classification of proteins with respect to their function (e.g. enzyme class or participation in a biological process like amino acid biosynthesis or energy metabolism) based on general sequence features that can be calculated (like sequence length, charge, and amino acid composition etc.) and prediction through the other methods on the server. Some of the resulting classifiers achieve a high level of 90% accuracy [235].

8.3 Protein Interaction Networks

In the late 1990s, cell-wide assays for measuring protein–protein interaction were developed. These assays are an extension of the yeast-two-hybrid (Y2H) method [236] to a large scale [237]. Without going into the details of the experimentation, the procedure basically aims at providing a binary matrix of size number of proteins × number of proteins that tells for each pair of proteins, whether they interact or not. With a different procedure called *tandem-affinity purification*, one can latch onto a protein and pull out with it a whole attached complex of proteins. The result is not a binary matrix but a set of protein complexes [238]. These data facilitate the bioinformatics analysis of cell-wide protein networks. The main problem is that both procedures are hampered by significant numbers of false negatives and false positives. A reason for this is that the laboratory procedures do not faithfully recreate the conditions under which the proteins bind in the cell. As a consequence, especially, the laboratory procedures cannot distinguish between transient binding partners and those that bind to each other over longer time periods, nor can they distinguish between binding events in different physiological states. Nevertheless, there have been preliminary attempts to mine the resulting protein interaction data with bioinformatics methods [239–242]. For an overview, *see* [243]. Most of these methods are based on the unsupervised learning paradigm; they are some form of clustering. The idea is that interacting proteins share some function. This guilt by association approach can also point to interesting drug targets [244]. Global topological properties of the networks are investigated, as well [245, 246]. However, it seems evident, that protein interaction data are most meaningfully analyzed in context with other data on protein function (*see* Sect. 8.7). Public data repositories for protein interaction data are also growing in volume [247] [248].

8.4 Genomic Context Methods

Even in the absence of mRNA expression or protein interaction data, there are several ways to learn about protein function from sequence data alone. The main prerequisite is that we need to have the complete genome in order to be able to reason not only about the presence but also about the absence of a protein. Since today there are many completely sequenced genomes available, especially in the prokaryotic domain, these so-called genomic context methods are quite effective. As a rule of thumb, we need roughly 30 genomes to reason about functional associations in proteins on the basis of the genome sequence. For eukaryotes, this number is not quite reached yet. Thus, genomic context methods are not yet effective in the eukaryotic domain.

In general, the genomic context methods uncover functional associations between proteins that are more general than the proteins that are binding partners. The proteins can also be functionally associated by taking part in the same biological process (cell cycle, apoptosis, etc.) or by cooperating in producing a phenotype (genetic association). We now list several genomic context methods.

Gene neighborhood and gene order Two proteins in two different species are more likely to be functionally associated if they occur in close proximity and in the same order along the genome in many species.

There are two variants of this method, one that respects the order in which the genes occur along the genome [249] and the other that does not [250]. A generalization of this method to more general conservation patterns that present cycles of association that alternate between homology and neighborhood has been presented in [251, 252].

Domain fusion This method rests on the observation that two proteins whose genes are fused in some other organism are more likely to be binding partners [253, 254].

Phylogenetic profiles This method rests on the observation that two proteins that are either present together in a species or absent together have a higher likelihood to be functionally related [255]. The cross-species comparison is based on an orthology test that has originally been reduced to a minimum value for evolutionary distance of the two proteins that is supposed to represent orthology. More recent and effective versions use gradual levels of evolutionary distance.

In general, genomic context methods are applicable nicely to prokaryotes but not as much to eukaryotes. The reasons are that too few eukaryotic genomes are fully sequenced to draw solid conclusions from genomic context hand also that the organization of genes in prokaryotes (e.g. their collection in operons) lends itself better to genomic context methods.

8.5 Function from Structure

Protein structure harbors detailed information on molecular function, since it is because of its structure that a protein acts the way it does. Still, the automatic deduction of information on protein function from protein structure is difficult and not extensively developed yet. Protein structure by itself is not indicative of protein function, since folds are often reused for different functions through gene duplications or convergent evolution. On the other hand, the same function (e.g. enzymatic class) can be realized with several protein folds [256]. A detailed orthology analysis can help here (*see* Sect. 8.2). Beyond this, remote homologies can hint at functional relationships, if not identify in function. For instance, two remotely homologous enzymes can share the same reaction mechanism, while substrate specificity is not conserved [257].

Just as sequence alignment is the methodical basis for analyzing the similarities and evolutionary relationships between protein sequences, structure comparison serves this purpose for protein structures. Structure comparison of proteins is mostly performed by structurally superposing the two (rigid) protein structures. The structural superposition of two proteins entails two subproblems. One is to align the two protein chains structurally. This means that we match the amino acid residue pairs, one in each protein that correspond to each other spatially, that is, take each other's place in the protein structure. Algorithmically, this alignment problem is the same as in sequence alignment, but the scoring function now has to represent structural similarity rather than sequence evolution, and is therefore different. Also, it is harder to assume the independence between alignment columns (*see also* Sect. 3.1), since residues that are adjacent in the protein structure influence each other. Several automatic methods for the structural superposition of proteins that have been developed are available on the Internet,

and have given rise to databases of structural protein classifications [258–262]. A recent evaluation of these servers is presented in [263]. The most widely used automatically derived structural classification of proteins is CATH [264] that uses the structural superposition method SSAP [265]. This database is only rivaled by the database SCOP that achieves a higher classification consistency, because it is manually curated [266].

Structural motifs in proteins, notably, specific ligand binding sites, can hint at functional aspects of proteins. Methods for automatically detecting such patterns have been presented in [267–271]. The calculation of statistical significance for the occurrence of a motif is a critical issue, just as it is for sequence search. Progress in this direction has been made, as presented in [272].

The location of functional sites along the protein surface is a very important aspect of bridging the gap from structure to function in proteins. Early methods had concentrated on geometric analysis, that is, they had looked for clefts and invaginations along the protein surface [273]. Physicochemical properties had soon been included in the analysis [274–276]. More recently, the evolutionary conservation of functional residues have been explored to identify functionally relevant regions on the protein surface [277, 278]. An important ingredient of the method is an accurate molecular clock measuring the speed of evolution [279]. The ConSurf Server makes the methods available over the Internet (http://consurf.tau.ac.il/) [280].

8.6 Text Mining

The most voluminous data source for protein function information is the literature but it is also hardest to digest by a computer. Text mining subdivides into two major disciplines, namely, information retrieval and information extraction. Whereas the first task is concerned with retrieving documents according to user-defined criteria, the more ambitious task of information extraction tries to ascertain facts about prespecified types of events, entities, or relationships described in the literature. Text mining methods have been established predominantly in the newswire domain. Whereas articles in that domain aim at a general audience, biomedical articles usually target a small community of domain experts, and, thus, are more difficult to interpret. The adaptation of methods to the characteristics of the biomedical literature has only begun. Available approaches employ natural language processing techniques to varying extents ranging from direct pattern matching approaches [281] to customization of established natural language processing systems [282].

In the biomedical context, one of the ultimate goals is the correct extraction of relationships among biological entities, such as proteins, genes, or diseases. Current text mining methods fail in this general setting owing to (1) general natural language processing problems, for example, tracking references to one object throughout the text or correctly identifying negations or hypotheses, and (2) domain-specific issues, such as the highly variable gene and protein nomenclature. Special purpose approaches with promising performance have been reported, however. For example, the extraction of facts pertaining to protein subcellular localization [283] or protein–protein interactions [282] has been addressed. Recently, an approach combining information retrieval and extraction for determination of protein–protein interactions has been reported, which relies

on machine learning techniques [284]. The system is used as an aid for curating the BIND database of protein interactions. The details of the approaches are beyond this review, but recent overviews are given by [285–288].

Still, text mining is an exploratory field that needs to improve methods and develop an evaluation standard [289]. In general, information retrieval methods provide sufficient performance to be of immediate use [284]. Information extraction results, however, should be assessed in the context of additional data or taken as starting points for database entries maintained by domain experts. To foster an exchange of ideas and determine most suitable algorithms for retrieval and extraction tasks, critical assessment contests must be implemented [289]. Toward this goal, the established TREC (http://trec.nist.gov/) conference on text mining methods has started a genomics track. Also, the BioCreAtIvE (Critical Assessment for Information extraction Systems in Biology) (http://www.pdg.cnb.uam.es/BioLINK/BioCreative.eval.html) competition has been launched in 2003 for comparison of text mining methods in the biomedical domain.

8.7 Information Integration

No single method for predicting protein function can do the trick by itself. Many of the methods even have problems reaching well above the noise level with respect to the accuracy of their predictions. Therefore, a central goal is to combine the different methods, in order to increase the reliability of the predictions. By now, we have collected quite a few methods that can contribute: sequence analysis and motifs, protein interaction data, literature data (extracted by hand or automatically), mRNA expression data, and protein interaction data. There are quite a few efforts to combine these methods. Methods evaluating protein interaction data in concert with mRNA expression data have been put forth [290, 291]. Marcotte et al. have presented the first study integrating several genomic context methods with primary experimental data and mRNA expression data [292]. The Bork group has followed first with two studies, a paper with the center around genomic context methods [293] and one with the center around protein interaction data [294]. More recently, they provided a world wide web-accessible database STRING (http://string.embl.de/) [295] of precomputed functional associations based on genomic context data that they validated in an experiment of recovering functional modules in *E. coli* [296]. All of these studies indicate that the methods are much stronger in concert than a single method by itself [297–299]. Also, domain fusion provides strong signals but is applicable only to a small subset of the proteins. Phylogenetic profiles seem to be the most powerful genomic context method. Surprisingly, mRNA expression data and protein interaction data carry comparatively little signal. Protein interaction data have been put into the context of other sources of signals for protein function by [294, 300, 301].

9 Analysis of Genetic Variations

So far, we have only considered the generic genome of a species and not made differences between the individuals. Of course, there is a lot of significance in analyzing these differences. In the human, the differences explain what distinguishes us

from each other, not only in appearance but, more importantly in our predisposition to diseases and our response to certain drugs. But not just the differences between individual human genomes are relevant. The individual differences in the genomes of the infectious agents (bacteria and viruses) that are the basis of diseases hold the key to understanding phenomena of resistance to drug treatment and, in concert with the genome of the host, to understanding problems or benefits of immune response. Therefore, we have to commit a few remarks to genetic variations in both contexts.

9.1 Genetic Variations in the Human: Analyzing Predispositions

Human genomes differ from each other in about 1 in 1200 base pairs. These differences, the so-called *single-nucleotide polymorphisms* (SNPs) are the data to be mined for the analysis of genetic predispositions for diseases and individuals responses to drug therapy. Monogenic diseases, that is, diseases that are caused by alterations in a single gene, such as sickle-cell anemia (caused by an SNP in the hemoglobin gene), cystic fibrosis, or hemophilia, have been studied for many decades. Roughly 5000 such diseases are known. Information on disease-relevant mutations and the related phenotypes is collected in the OMIM database [302].

Genes for monogenetic diseases can be found by classical methods of statistical genetics. Specifically, there are two such methods. Both of them rely on molecular markers – short, polymorphic stretches of repetitive DNA or SNPs – which vary between people. These polymorphisms can be identified for different people, some of which carry the disease and some of which do not. With the help of statistical procedures, one can ascertain, which instance of the marker is related to the disease. If a significant correlation between a certain instance of the marker and the disease can be detected, this is evidence of the fact that a gene involved in the disease may lie close to the location of the marker. The probability that the gene is involved in the disease decreases with the distance of the gene from the marker. A statistical score, the so-called LOD (log-odds) score quantifies the likelihood of the gene being involved in the disease. Experimental or bioinformatics procedures follow that screen through a high-scoring genomic region, in order to uncover candidate genes and determine their function. The two methods from statistical genetics differ in the sort of data that they analyze. *Linkage analysis* analyzes familial data, that is, pedigrees of families in which the disease is running. These data are usually sparse and hard to come by, but if they are available, they provide more detailed insight into the genetic basis of the disease. *Association analysis* analyzes more voluminous data taken from larger populations, however, without being given any familial relationships [303–305]. Though no monogenetic disease is curable, today, we have a lot of knowledge on the molecular basis of many of these diseases much of which has implications on therapy. Unfortunately, most of the widespread diseases cannot be reduced to a defect in a single gene. Rather, their causes are a mixture of alterations in many genes and influences of the environment. These so-called complex diseases are the center of genomic research targeting genetic differences between individuals. The identification of genes involved in complex diseases is much harder than that of monogenetic diseases [306, 307]. The Iceland genotyping effort is providing a unique database

for studying the genetic basis of complex diseases [308]. This program aims at genotyping the total Icelandic population, in principle, and relating these data to the extensive pedigree information that this country has collected for almost one thousand years. The company deCODE Genetics, Inc. [309] has been formed, for this purpose. The project is carried out in cooperation with the pharmaceutical company Hoffman–LaRoche and has stirred much controversy [310–314] and required special legislation in Iceland [315]. A few years after its start, the project has turned up 15 disease genes and mapped genes linked to more than 25 common complex diseases (http://www.decode.com/).

The next step after identifying genes related to a disease is selecting targets for drug design and developing related drugs. The field that uses genomics for drug-related research, not necessarily regarding inter-individual differences, is often called *pharmacogenomics* [316, 317]. (However, frequently, this notion is also used with the meaning of the word *pharmacogenetics* below.) All experimental and bioinformatics technologies described above can be employed for this purpose. Notably, mRNA microarrays are under intensive investigation [318]. Furthermore, comparative genomics analysis can help transfer knowledge that is relevant for target finding and drug design from organisms that are easier to handle experimentally to the human [319, 320].

As inter-individual differences enter the investigation, the term *pharmacogenetics* [321] is used increasingly frequently, instead of *pharmacogenomics*. (However, there are also different distinctions between the two notions in the literature [322, 323].) Special challenges for bioinformatics in this context are reviewed by Altman and Klein [324]. This group also takes on a major challenge, namely the collection of relevant data in the database PharmGKB (http://www.pharmgkb.org/) [325]. This database collects genomic, phenotypical, and clinical information relevant for pharmacogenomics, and the related project is developing tools for interlinking and querying the data and visualizing the responses, as well as developing strategies for maintaining confidentiality and privacy of critical data. Beyond data handling, bioinformatics analysis of pharmacogenetic data include the investigation of structural and functional consequences of nonsynonymous SNPs, that is, polymorphisms that alter the protein sequence [326]. SNPs in the regulatory regions of genes have a more subtle effect on the binding of transcription factors and are harder to analyze with bioinformatics methods. The author is not aware of any result in this direction.

9.2 Genetic Variations in Pathogens: Analyzing Resistance

It is evident that the analysis of the genome of a pathogen and its relationship to the host can uncover the molecular basis of pathogenicity. There is a multitude of research in this area, too much to survey here. Overviews are presented in [327–331].

Here, we focus on the phenomenon of resistance based in genetic variations of the pathogen. Infectious diseases are characterized by a dynamic and dramatic battle between a population of a microbial pathogen and the immune system of the host. Drug therapy is supposed to either target the pathogen directly or support the action of the host's immune system. In

the course of this process, the pathogen responds to the selective pressure exerted by the drug treatment by preferentially evolving into resistant variants. Understanding this process necessitates an analysis on the genomic level, at best involving both the pathogen and the host. Bioinformatics can help in this process. The research area is quite new. Therefore, we will only present one example relating to HIV/AIDS.

HIV is a rapidly mutating virus that attacks the immune system of the host. Currently, there are almost twenty drugs in the marketplace that target viral proteins. Since the virus changes rapidly under drug pressure, in the *Highly Active Anti-retroviral Therapy* (HAART) scheme, combinations of drugs targeting different viral proteins are given. Still, within weeks, a resistant strain of the virus develops, and a new drug combination has to be selected. This combination should not only be effective against the currently existing viral strain but also make it as hard as possible for the virus to become resistant. The selection of drug combinations can be aided with bioinformatics methods. To this end, two kinds of data are collected: (1) genotypic resistance data relating the genotype of the viral strain prevalent inside the patient to clinical disease measures (here the number of virus particle in one µL of blood serum) and (2) phenotypic resistance data originating from laboratory experiments, in which viral strains are exposed to HIV drugs and the so-called resistance factor is measured. The resistance factor is the quotient of the drug concentration that halves the growth of the tested virus strain divided by the respective concentration for the wildtype. There are several databases collecting resistance information (http://resdb.lanl.gov/Resist_DB/default.htm) (http://hivdb.stanford.edu/) (A new development that has not generated any publications yet is *the HIV Resistance Response Database Initiative* http://www.hivrdi.org/) [332, 333]. Bioinformatics approaches to data analysis take a viral genome as input, and report estimate of effectivity of single drugs [334, 335] and drug combinations, including an estimate of the shortest mutational path to resistance [336].

10 Basic Bioinformatics Technologies

So far, this chapter was organized according to application-oriented problem domains in bioinformatics. At the end of the chapter, we want to take a more methodical viewpoint and summarize basic information technology concepts as they pertain to the field.

10.1 Databases

As has become evident throughout the chapter, data handling, curating, and interlinking is central to bioinformatics. There are a tremendous number and variety of biological databases that contribute to the field, many of them accessible via the Internet (*see* Sect. 11). The databases are developed in very different settings and use different solutions for IT concepts, data curation, and data presentation. This results in an inhomogeneous, if not to say, chaotic data landscape that integrative concepts in bioinformatics have to deal with – an almost unmanageable task.

Several approaches have been followed to integrate the various databases [337].

Link integration This approach leaves the databases as they are and, indeed, where

they are and maintains cross-links between the related data records in different databases, using the application interfaces provided by the databases. This strategy is haphazard, but it is practical since, while it is helpful to cooperate with the providers of the database, it is not necessary to do so. Link integration is the technology for most small and medium integrative bioinformatics projects. The sequence retrieval system (SRS) (http://srs.ebi.ac.uk/) [338] is a variation of this technique. It adds a central keyword indexing and search system to the linking paradigm. SRS is more sophisticated than the usual Internet search engines, because it recognizes the existence of structured fields in source databases and can link between related fields in different databases. The advantages of link integration are also its disadvantages: it is basically an uncoordinated effort of database integration, and therefore it is especially vulnerable to changes of the source databases and notational and data-structural inconsistencies.

View integration This is somewhat more complex than link integration. Again the data are left in their source databases. This time, however, an environment is built around the source databases that makes them all look like one unified database. To this end, a front-end query machine is created that parses a query, decides which databases have to be accessed, generates the subqueries to these databases, retrieves the results, and combines them to answer the query in a unified manner. The most complex system of this sort reported in the literature is the K2/Kleisli System [339]. This approach is not as popular with the users as link integration, possibly because of performance issues.

Data warehousing This is the most complex variant. Here, all data are collected from their source databases in one system under a unified database model. Tools for querying and navigation can now be integrated deeply with the data model and one has maximum control over issues of data consistency and updating. However, the effort to create a data warehouse is gigantic, and the incremental import of new information (and possibly update of old information that has been revised) is a highly nontrivial issue. Also, data models for warehouses tend to evolve, and this causes significant strain on the system, which has to stay operable in the process. An early ambitious data warehouse project was the Integrated Genome Database (IGD) [340], which was aimed at integrating sequence data with physical and genetic maps. This warehouse included more than a dozen source databases, but only held for a year. A current data warehouse project is the Genomics Unified Schema (GUS) project by IBM [341]. This project is more modest in that it only supports a number of in-house research projects and does not aspire to become a public resource.

10.2 Visualization

Visualization of bioinformatics data and analysis results are central to the acceptance of bioinformatics tools, as a whole. There are several issues to visualization.

Molecular visualization In the eighties, molecular structures found their way from the laboratory table into the computer. Beyond the revolutionary technology in hardware and software that afforded us with methods for rendering complex 3D molecular structures under controllable and realistic light conditions, central contributions

to the field included algorithms for computing molecular surfaces [342]. In principle, the graphical representation of molecular structures by computer is a mature field, whose main remaining challenges are in performance increases in order to allow for the interactive manipulation of ever more complex structures and in usability issues.

The situation is a little different if molecular motion is involved. Here, we can benefit from more help in order to visually structure complex modes of motion in large molecules or molecular complexes. Morphing algorithms are employed here that take molecular characteristics, specifically the normal modes of molecular vibrations, into account if only the starting and final state of the motion are available [343, 344]. Similar algorithms do not seem to exist for actual molecular dynamics trajectories.

Visualization of high-dimensional data Almost all analysis procedures in bioinformatics have a serious visualization problem, when it comes to presenting the results of the analysis to the user. For instance, many bioinformatics methods deal with high-dimensional data. The number of dimensions can be extraordinarily large. It can reach into the hundred thousands. Often, statistical procedures are applied to the data. The results then have to be visualized in some fashion. Usually, some kind of dimension reduction is applied, for example, using principal component analysis or independent component analysis [196]. Self-organizing maps [345] and locally linear embedding [346] are nonlinear methods for reducing the number of dimensions in a dataset while preserving neighborhood relationships between the data points. However, in general, the problem of visualizing high-dimensional data sets is far from being solved.

Visualization of graphs Other structures that have to be visualized are large unstructured graphs (e.g. protein interaction networks [347, 348]) or structured graphs with complex application specific boundary conditions (complex metabolic or regulatory networks, *see* [349, 350]). Large trees (phylogenies or hierarchical clusterings [351]) also present a challenge for visualization. Here, zooming and refinement approaches can help. Similar methods are used in genome browsers for covering several orders of magnitude in scale regarding genome sequences. In general, methods of visualization will have to be developed that utilize generic methods but are tailored to the biological application domain.

10.3 Internet

The Internet has become the central medium of bioinformatics. In addition to being the forum for providing literature, data, and methods, it is the backbone for many integrative approaches. Standards have been developed for exchanging data over the Internet, such as the distributed annotation system (DAS), which supports the exchange of genomic annotation information. The genome browser Ensembl (http://www.ensembl.org/) [352, 353] uses DAS to allow third-party providers to add their additional annotations to its canonical annotations of genes. There are two projects extending DAS, BioMOBY, and ^{my}Grid. BioMOBY [354] allows for registering services together with a description of their input and output, in order to better chain bioinformatics procedures.

myGrid [355] goes a step further by using grid computing technology [356] to describe precisely how different bioinformatics services are related, how they can be located and invoked on a large resource of processors available via the Internet. This necessitates the use of ontologies for describing bioinformatics services. Thereby, myGrid does not require a central registration system.

In some sense, genome browsers are the ultimate bioinformatics resource. They are the search engines tailored to biology. Ensembl, the University of California Santa Cruz Genome Browser (http://genome.ucsc.edu/) [357], and the Entrez Genome Site at NCBI (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=Genome) [358] are the most popular genome browsers on the Internet. Ideally, they should assemble all biological information relevant to and derivable from the genome sequence. As it is, they currently focus on gene identification and are still lacking much of the downstream structural and functional annotation. The future will see the browsers continually fill with biological information, as it is uncovered by exercising bioinformatics and experimental methods, in concert.

11 Can we Trust Bioinformatics Predictions?

Throughout this chapter, not only the potential but also the limitations of today's bioinformatics have become apparent. Bioinformatics is plagued by inconsistent and often defective data, by heuristic algorithms that do not find the optimum that they are looking for and by models and scoring function that represent the situation they want to model only inaccurately. As a result, we cannot expect the prediction of bioinformatics procedures to be flawless. Rather, up to now, we have had to deal sometimes with substantial margins of error. There are three ways to cope with this phenomenon.

1. Be aware of it. As long as results from bioinformatics procedures are treated as suggestions and not as facts, we basically do not have a major problem. All bioinformatics predictions have to be thoroughly validated, most of them involving laboratory procedures. Still, even in the presence of high noise levels, bioinformatics procedures can limit the search space significantly, for example, when looking for drug targets or drugs. In the latter case, for instance, this is the basis for the scientific and commercial success of protein–ligand docking and drug-screening programs. Rather than finding the drug candidate unfailingly, they enrich the number of hits among the high-ranking molecules in the screen. This is sufficient in practice (at least for now) and leaves room for continual improvement. The situation is not much different in many other domains of bioinformatics.
2. Invest in data curation. Primary data are at the beginning of the bioinformatics food chain. If they are faulty, the errors will propagate. The landscape of bioinformatics databases is populated with a dominant and growing number of *derived* databases. These are databases that apply bioinformatics procedures to primary data and produce derived data, such as protein structure models, gene predictions and so on. If the primary data are faulty, these errors will propagate through the food chain and spoil the whole bioinformatics meal. Actually, this is today's situation. Attempts are being made to

remedy it by introducing quality standards for data generation (such as the MIAME standard for mRNA expression data) and by investing much effort into curating at least the central primary databases. Also, scientific journals continually adapt and step up their policies for accepting papers reporting on experimental data with respect to quality control of the reported data. Conversely, bioinformatics procedures can help curate primary data. There are quite a few cases in which bioinformatics analyses turn up sanity checks for biological data as a side product (*see*, e.g. [58, 359–361]), and it is confounding how many errors are being found. Nevertheless, the data curation problem remains difficult if not insurmountable and is one of the central bottlenecks of the whole field.

3. Assess the reliability or confidence of a bioinformatics prediction. Doing so requires a significant amount of work. In some very restricted settings, there are theoretical results that allow for deriving a significance value (sometimes called *p*-value). One prominent example is gapless alignment [18] (*see also* Sect. 3.1). In other cases, there is no theory, but heuristic statistical procedures allow for assessing the probability that the resulting prediction is just a product of chance rather than a consequence of some underlying biological phenomenon. This is the case whenever we have a reproducible distribution of scores rating the predictions. Then, we can formulate a null model against which we rate the prediction. The global sequence alignment with gaps has been done by [362], for instance. Statistical significance has been studied in a growing number of bioinformatics domains, such as protein threading, finding motifs in protein sequences and structures, and the analysis of mRNA expression data. Since exact predictions are not to be expected, accurate measures of statistical significance are the primary methodical contribution toward making bioinformatics predictions more usable.

In the future, we will see a considerable expansion of the field of bioinformatics, in terms of the variety and volume of the data, as well as in terms of the number of methods and the amount of integration. Bioinformatics is an essential part of biology and medicine already today. As it develops further and integrates more with laboratory experimentation, it will expand its role as the third major pillar of modern life science in addition to laboratory experimentation and theoretical biology.

Keywords

Innate Immunity
An evolutionally conserved immune system utilizing germline-encoded pattern-recognition receptors.

PAMPs
Pathogen-specific molecular patterns recognized by host pattern-recognition receptors.

TLRs
Pattern-recognition receptors that detect pathogen-derived components and are composed of extracellular leucine-rich repeats and a cytoplasmic TIR domain.

TIR Domain
A domain shared by the cytoplasmic portions of TLRs, IL-1R family members, and adaptor proteins that mediate signal transduction.

NOD-LRR Family
Pattern-recognition receptors composed of C-terminal leucine-rich repeats, a central nucleotide-binding oligomerization domain, and N-terminal protein–protein interaction motifs, such as caspase recruitment domains, pyrin domains, or a TIR domain.

The innate immune system utilizes a limited number of germline-encoded pattern-recognition receptors to sense invading pathogens, and is evolutionally conserved from *Drosophila* to vertebrates. The mammalian innate immune system is subdivided into three different mechanisms. The first mechanism is the lectin-complement pathway, which recognizes invading microorganisms using plasma proteins such as lectin. The second mechanism is the Toll-like receptor (TLR) pathway, which detects pathogen-specific molecular patterns (PAMPs) shared by broad classes of microorganisms via TLRs on the membranes of innate immune cells. Each TLR activates a distinct signaling pathway by recruiting different TIR-domain containing adaptor molecules. The pathways lead to activation of the transcription factors NF-κB, AP-1, and interferon regulatory factor 3 (IRF3), followed by rapid induction

of proinflammatory cytokines and type I interferons (IFNs). The third mechanism is mediated by cytoplasmic pattern-recognition receptors that detect microorganisms in the cytosol, and also leads to the production of cytokines and IFNs. These innate responses also instruct acquired immunity by expressing costimulatory molecules and presenting antigens for recognition by lymphocytes.

1 Innate Immunity

In vertebrates, the immune system consists of both innate and acquired immunity, which are defined on the basis of their mechanisms for detecting the presence of infectious organisms. The innate immune system is characterized by the use of a limited number of germline-encoded receptors that recognize diverse pathogens invading the host. The innate system, therefore, targets a set of molecular structures that are absent from host cells, but are unique to microorganisms and shared by various pathogens. By recognizing these ''pathogen-specific'' patterns, the innate system is able to prevent autoimmune responses. For instance, lipopolysaccharide (LPS), bacterial lipoprotein, peptidoglycan (PGN), lipoteichoic acid (LTA) and double-stranded RNA (dsRNA) are synthesized by bacteria or viruses, but not by host cells. Furthermore, carbohydrates such as mannose and *N*-acetylglucosamine on the surface of pathogens also represent targets for recognition.

The innate immune recognition is mediated by three different mechanisms. The first mechanism is the lectin-complement pathway, which is mediated by lectins and complement proteins secreted into the extracellular space. Binding of lectin to a microorganism triggers a chain of reactions on the surface of that microorganism leading to its destruction or opsonization. The second mechanism is the Toll-like receptor (TLR) pathway, which is mediated by transmembrane receptors on innate immune cells such as macrophages and dendritic cells (DCs). Detection of microorganisms by TLRs activates the cells to produce proinflammatory cytokines and chemokines to evoke inflammation and to recruit immune cells to the site of the infection. In addition, TLR pathways can induce maturation of DCs to instruct and adequately activate acquired immunity. The third mechanism is mediated by cytoplasmic pattern-recognition receptors that detect viruses and bacteria that have successfully invaded cells.

In contrast, the acquired immune system generates a highly diverse repertoire of antigen receptors, T- and B-cell receptors, via DNA rearrangement then followed by clonal selection that eliminates self-reacting cells. After encountering a pathogen, the lymphocytes bearing appropriately high affinity antigen receptors for that pathogen expand and eliminate the pathogens in the late stage of infection and contribute to the establishment of immunological memory. However, recent studies have revealed that adequate instruction by innate immune cells is a prerequisite for the activation of lymphocytes.

The innate immune system is evolutionally conserved from *Caenorhabditis elegans* and *Drosophila melanogaster* to vertebrates. In fact, it should be noted that *Toll* was originally identified during

research into *Drosophila* developmental biology, and its role in *Drosophila* immune responses has been extensively studied. Moreover, the knowledge gained from that research has had a tremendous influence on advancing research into mammalian innate immunity.

2 *Drosophila* Immune Response

Drosophila does not possess the adaptive immune system, and mounts its host defense by discriminating between classes of pathogens and inducing immune responses. An important part of *Drosophila* immune response is the synthesis of antimicrobial peptides against microbial infection. *Drosophila* has seven antimicrobial peptides, and among those, Drosomycins and Metchnikowin have activity against fungi, Defensin acts against gram-positive bacteria and Attacins, Cecropins, Drosocin, and Diptericins have spectra against gram-negative bacteria. The induction of appropriate antimicrobial peptides is regulated by two distinct signaling pathways, *Toll* and *Imd*. The *Toll* pathway is activated in response to infections by fungi and gram-positive bacteria. Toll is a receptor that contains extracellular leucine-rich repeats and a cytoplasmic Toll/IL-1R homology domain. It was originally identified as an essential component of the pathway that determines the dorsal-ventral axis in early *Drosophila* embryogenesis, but *Toll*-mutant flies were also found to be susceptible to fungal infection. Invading gram-positive bacteria are recognized by PGN-recognition proteins (PGRP) followed by activation of a Toll ligand, Spaetzle. Binding of Spaetzle to Toll activates the *Drosophila*homolog of MyD88 and a serine/threonine kinase, Pelle, followed by the phosphorylation and degradation of Cactus, an IκB like inhibitory protein of Rel-type transcription factors. The degradation of Cactus releases the transcription factors Dorsal and Dorsal-related immunity factor (DIF) and initiates their nuclear translocation to induce the expression of Drosomycin genes. The pathway closely resembles the mammalian TLR- and interleukin-1 receptor (IL-1R)-mediated signaling pathway. In *Drosophila*, the Toll family consists of nine members, but the other Toll family members may not be involved in antimicrobial immune response.

The *Imd* pathway is involved in host defense against gram-negative bacteria by inducing Attacins, Cecropins, Drosocin, and Diptericins. The IMD protein contains a death domain (DD) that has high homology to that of mammalian TNF-receptor interacting protein (RIP). *Drosophila* homologs of FADD, TGF-β-activated kinase 1 (TAK1), IκB kinase (IKK) β are involved in the *Imd* pathway. Activated *Drosophila* IKKβ phosphorylates another NF-κB like protein, Relish, which results in its cleavage and subsequent nuclear translocation. In turn, Relish induces the expression of genes encoding antimicrobial peptides against gram-negative bacteria. Gram-negative-binding proteins (GNBPs) and a member of the PGRP family containing a transmembrane domain have been implicated in the *Imd* pathway, but the precise mechanisms for *Imd* pathway activation by these molecules remain to be clarified.

Taken together, *Drosophila* distinguishes among different types of invading microorganisms by activation of distinct signaling pathways, resulting in the production of appropriate antimicrobial peptides for the particular type of invading pathogen.

3
The Lectin-complement Pathway

In mammalian innate immunity, the lectin-complement pathway is an important mechanism for recognizing a wide range of pathogens outside of host cells, and is mediated by a number of proteins that are secreted into the serum. The lectin pathway involves carbohydrate recognition by mannose-binding lectin (MBL) and ficolins (Fig. 1). MBL and ficolins specifically recognize *N*-acetyl-D-glucosamine (GlcNAc), mannose, and fucose, and do not interact with D-galactose or sialic acid, which are abundant on mammalian cells. Binding of MBL and ficolins to microbial carbohydrates activates members of the MBL-associated serine protease (MASP) family on the surface of bacterial cells. MASPs, which form complexes with MBL, are enzymes that cleave complement components to activate the complement pathway (Fig. 1). The cleavage leads to direct destruction of the invading bacteria or to their opsonization, which facilitates phagocytosis by macrophages, and in human, MBL-deficiency was shown to increase susceptibility to a variety of infectious diseases. Among MASPs, MASP-2 is responsible for activation of C4 and C2, which leads to C4bC2a enzyme complex formation. C4bC2a then acts as a C3 convertase and cleaves C3, generating products that can bind and destroy bacteria. In contrast, MASP-1 is able to cleave C3 directly (Fig. 1). Together, the lectin-complement pathway plays an important role in detecting microorganisms in the bloodstream and in extracellular space.

4
Toll-like Receptors (TLRs)

In 1997, Janeway and Medzhitov identified a mammalian homolog of *Drosophila* Toll and showed that it was involved in the innate immune response. Eleven mammalian TLRs have been reported to

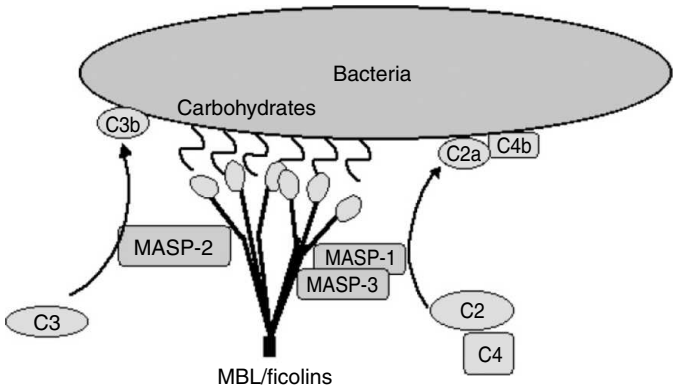

Fig. 1 The lectin-complement pathway. MBL or ficolin binds bacterial carbohydrates on the surface of a bacterial cell. This results in the activation of MASP family members that associate with MBL or ficolin. MASP-2 is responsible for catalyzing cleavage of C4 and C2 to generate C4b and C2a. A C4bC2a complex catalyzes the cleavage of C3, resulting in the generation of C3b that binds to and destroys the bacteria. In contrast, MASP-1 and -3 cleaves C3 directly.

date, and 10 of them have been shown to recognize specific PAMPs. TLRs (Toll-like receptors) are expressed not only on macrophages, DCs, and B cells, but also on fibroblasts, vascular endothelial cells, and intestinal epithelial cells. The TLR family proteins consist of extracellular leucine-rich repeat (LRR) motifs, a transmembrane region, and a cytoplasmic tail containing a Toll/IL-1 receptor homology (TIR) domain. The LRR motifs are responsible for ligand recognition and the TIR domain is essential for triggering intracellular signaling pathways. The activation of TLR signaling pathways leads to the expression of proinflammatory cytokine and chemokine genes. This induces migration of immune cells from peripheral blood to the site of infection. DCs play a pivotal role in T cell activation and differentiation into T helper 1 cells. DCs phagocytose pathogens, process them, and present the antigenic peptides on MHC molecules. TLR signaling is critical for the maturation of DC by regulating phagosome maturation, costimulatory molecule expression and cytokine production.

Homeostasis of acquired immunity is controlled by regulatory T cells, which can suppress self-reacting T cells. However, regulatory T cells do not interfere with T cell activation in the course of pathogenic infection. Recent studies revealed that TLR signaling is involved in suppression of the inhibitory function of regulatory T cells. This is controlled by IL-6 secreted by TLR stimulation.

In addition, ligands for TLR3, TLR4, TLR7, and TLR9, but not for TLR2 and TLR5, are known to upregulate type I interferons (IFNs) and IFN-inducible genes. These TLRs recognize viral as well as bacterial components, indicating that TLR signaling is also involved in antiviral immune responses. Roles of each TLR in the recognition of bacterial components are described in the following section (Fig. 2).

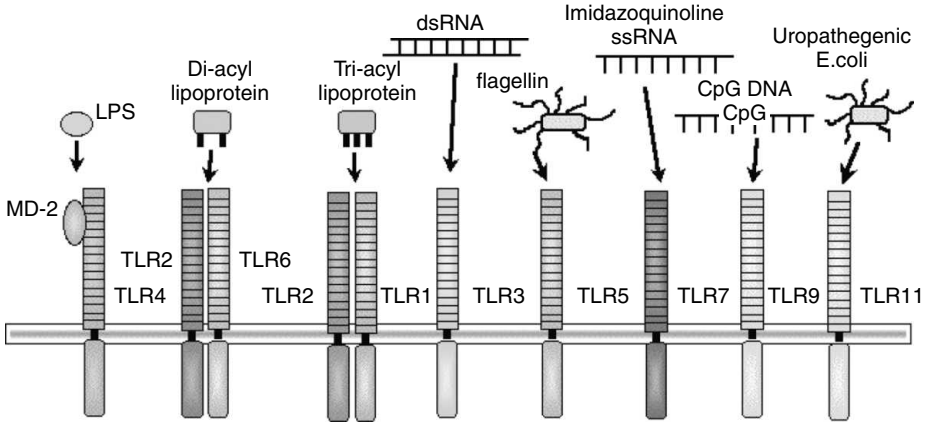

Fig. 2 TLRs recognize various PAMPs. TLR2 recognizes bacterial lipoproteins in concert with TLR1 or TLR6. TLR1 and TLR6 discriminate subtle difference in the lipid moiety of tri-acyl and di-acyl lipoproteins, respectively. TLR4 forms a complex with MD-2 and detects LPS. TLR3 is involved in extracellular recognition of viral dsRNA and TLR5 recognize bacterial flagellin. TLR7 and TLR9 are responsible for viral ssRNA and unmethylated CpG-DNA, respectively. TLR11 detects uropathogenic bacteria in mice.

4.1 TLR2

TLR2 recognizes various PAMPs from bacteria, fungi, and parasites including bacterial lipoprotein, PGN, *Saccharomyces cerevisiae* zymosan, and glycosylphosphatidylinositol (GPI)-anchors from *Trypanosoma cruzi*. In addition, TLR2 is involved in the recognition of LPS from *Porphyromonas gingivalis* and *Leptospira interrogans*, which have different structures to LPS from enterobacteria. Macrophages derived from TLR2$^{-/-}$ mice did not produce proinflammatory cytokines in response to TLR2 ligands, such as PGN and bacterial lipoproteins, and TLR2 signaling did not induce type I IFNs. Corresponding to the failure to detect these components through TLR2, TLR2$^{-/-}$ mice were susceptible to infections by various gram-positive bacteria and fungi, including *Staphylococcus aureus*, Group B *Streptococcus, Borrelia burgdorferi*, *Chlamydia trachomatis*, *Candida albicans*, *Streptococcus pneumoniae*, and so on. On the other hand, recent reports have shown that TLR2 signaling suppresses immunity against *Candida* infection. The population of regulatory T cells and IL-10 secretion were partially reduced in TLR2$^{-/-}$ mice, which may explain the improved resistance to *Candida* infection. Although the precise mechanism of this suppression is to be clarified, this is an interesting phenomenon that TLR signaling can work as both stimulatory and inhibitory manner.

4.2 TLR1 and TLR6

TLR1 and TLR6 are highly homologous with each other and are also homologous to TLR2. Heterodimerization of TLR2 with TLR1 or TLR6 determines the ligand specificity. Although expression of either TLR1 or TLR6 alone failed to confer any response, coexpression of TLR1 or TLR6 with TLR2 resulted in cell activation in response to triacyl- or diacyl-lipopeptide, respectively. The cellular response to mycoplasmal diacyl-lipopeptide was abolished in TLR6$^{-/-}$ mice. In contrast, TLR1$^{-/-}$ mice showed an impaired response to triacyl-lipopeptide, while the response to diacyl-lipopeptide was normal. Overexpression studies revealed that TLR1 and TLR6 each interacted with TLR2 in cells. These observations suggest that TLR1 and TLR6 recognize the difference in the lipid portion of lipoproteins through heterodimerization with TLR2.

4.3 TLR3

Infection with RNA viruses leads to dsRNA generation in the cytoplasm of infected cells. Such dsRNA is a virus-specific molecular pattern that can be recognized by the host to stimulate immune responses. Cells expressing TLR3 respond to dsRNA or its synthetic mimic, polyinosinic-polycytidylic acid (poly I:C), and activate an intracellular signaling pathway leading to upregulation of type I IFNs and proinflammatory cytokines. Myeloid DCs and lung fibroblasts derived from TLR3$^{-/-}$ mice were hyporesponsive to poly I:C stimulation, and TLR3$^{-/-}$ mice were reported to be susceptible to cytomegalovirus (CMV) infection. However, inoculation of poly I:C into TLR3$^{-/-}$ mice resulted in normal production of serum IFNα, indicating that other molecule(s) are also involved in the dsRNA-induced immune responses.

4.4 TLR4

Two strains of mice, C3H/HeJ and C57BL/10ScCr, were known to be hyporesponsive to LPS, a component of outer cell membrane of gram-negative bacteria. Positional cloning of the gene responsible for LPS recognition in these mice identified TLR4. In C3H/HeJ mice, a missense point mutation resulted in replacement of a proline in the cytoplasmic domain of the TLR4 protein with histidine, and created a dominant-negative form of the protein. In C57BL/10ScCr mice, the *Tlr4* locus was entirely deleted. TLR4$^{-/-}$ mice generated by homologous recombination of embryonic stem (ES) cells were highly resistant to LPS-induced shock, and macrophages and B cells derived from these mice were unresponsive to LPS in terms of proinflammatory cytokine production and the proliferative response. The activation of NF-κB and MAP kinase in response to LPS was also abrogated. Moreover, C3H/HeJ mice were highly susceptible to infection by *Salmonella* and *Escherichia coli*, indicating that recognition of bacteria by TLR4 is critical to host defense

The entire LPS recognition machinery is more complicated. When LPS is present in the bloodstream, it is immediately captured by LPS-binding protein (LBP), and the LPS–LBP complex is transferred to CD14, a GPI-anchored protein, located on the surface of macrophages. An extracellular protein, MD-2, directly binds TLR4 and enhances LPS-induced NF-κB activation in the TLR4-expressing cells. LBP$^{-/-}$ and CD14$^{-/-}$ mice are hyporesponsive to LPS stimulation. The response of MD-2$^{-/-}$ mice to LPS was also severely impaired. Interestingly, surface expression of TLR4 was abolished in MD-2$^{-/-}$ macrophages. LPS stimulation initiates the dimerization of TLR4 to ignite the downstream signaling pathway. An LRR containing transmembrane protein, RP105, is also involved in LPS recognition in B cells, since targeted disruption of RP105 resulted in an impaired proliferative response of B cells to LPS.

In addition to LPS, TLR4 recognizes several other PAMPs such as respiratory syncytial virus F protein and mouse mammary tumor virus envelope protein. In addition, it has also been reported to recognize endogenous products. Under inflammatory conditions, components of the extracellular matrix are degraded or processed. The products, such as fibronectin fragments and hyaluronic acid degradation products can stimulate cells through TLR4. Furthermore, several studies have demonstrated that both human and chlamydial HSP60 are putative ligands for TLR2 and TLR4. However, it is possible that these ligand preparations were contaminated with LPS or other PAMPs, since most studies utilize recombinant proteins synthesized in *E. coli*.

4.5 TLR5

TLR5 recognizes bacterial flagellin, a unique PAMP composed of protein. Flagellin is a protein component of the flagellum, a structure used by some bacteria to move through liquid media. Chinese hamster ovary (CHO) cells expressing human TLR5 can activate NF-κB in response to flagellin. Moreover, *Salmonella typhimurium* lacking flagellin failed to activate TLR5, indicating that TLR5 is critical for flagellin recognition. A stop codon within the open-reading frame (ORF) of human TLR5 in many individuals renders them incapable of responding adequately to flagellated bacteria. The

MOLF/Ei mouse strain is shown to be susceptible to *S. typhimurium* infection, and one of the MOLF/Ei susceptibility loci was mapped to chromosome 1, which contains the mouse *Tlr5* gene. Furthermore, TLR5 expression was reduced in MOLF/Ei mice.

4.6 TLR7 and TLR8

TLR7 is closely related to TLR8 and shows significant homology with TLR9. TLR7 and TLR8 are both located on the X chromosome. Recent studies have revealed that the ligands of these three TLRs are nucleotides and their derivatives. Initially, imidazoquinoline derivatives, including imiquimod and resiquimod (R-848), were identified as TLR7 ligands in mice. These derivatives are small synthetic compounds that are approved for use as antiviral drugs due to their potency for inducing type I IFNs. TLR7$^{-/-}$ mice failed to respond to these compounds by producing proinflammatory cytokines or type I IFNs. In humans, R-848 strongly activates plasmacytoid DCs (pDCs) to produce IFNα. TLR7 is also involved in the recognition of other synthetic anticancer drugs, such as loxoribine (7-allyl-8-oxoguanosine), bropirimine (2-amin-5-bromo-6-phenyl-4(3)-pyrimidinone) and certain guanosine analogs. Recently, TLR7 was found to be essential for DCs to recognize single-stranded RNAs (ssRNAs) (Fig. 2).

Expression of human TLR8 as well as human TLR7 in HEK293 cells conferred the responsiveness to ssRNAs to activate an NF-κB reporter gene. In contrast, the expression of mouse TLR7, but not TLR8, could restore ssRNA response in culture cells. Moreover, antigen-presenting cells from TLR8$^{-/-}$ mice produced proinflammatory cytokines normally in response to ssRNAs, suggesting that human and mouse TLR8 recognize different PAMPs.

4.7 TLR9

Bacterial DNA is characterized by an abundance of CpG motifs and the lack of methylation. This PAMP is recognized by the host immune cells such as DCs, macrophages, and B cells, and strongly induce T helper 1 development. Furthermore, synthetic oligodeoxynucleotides containing an unmethylated CpG motif (CpG-DNA) show strong immunostimulatory activity.

TLR9 was shown to be essential for CpG-DNA detection, since the immune response to CpG-DNA stimulation was abolished in TLR9$^{-/-}$ mice. TLR9 is localized in the endoplasmic reticulum (ER) where CpG-DNA is transported after its incorporation into a tubular lysosomal compartment. DNA viruses, such as Herpes simplex virus (HSV) types I and II, also contain genomic DNA with unmethylated CpG motifs, and pDCs from TLR9$^{-/-}$ mice failed to produce IFNα upon HSV I or II infection. Moreover, mice with a mutation in the *Tlr9* locus were susceptible to CMV infection, indicating that TLR9 is critically involved in the immune response against DNA viruses.

4.8 TLR11

Mouse TLR11 is expressed in macrophages and liver, kidney, and bladder epithelial cells. Cells expressing TLR11 specifically respond to uropathogenic bacteria, but not to known other TLR ligands. TLR11$^{-/-}$ mice were highly susceptible to kidney infections by uropathogenic bacteria, and macrophages derived from TLR11$^{-/-}$

mice failed to produce proinflammatory cytokines in response to these bacteria. However, human TLR11 is likely to be nonfunctional, since the stop codons were observed in its ORF.

5 The TLR Signaling Pathway

By detecting PAMPs, TLRs trigger downstream Signaling pathways that lead to nuclear translocation of NF-κB and the activation of MAP kinases (Fig. 3). TIR domain-containing adaptors are recruited to the receptors first, and then interact with IL-1R-associated kinases (IRAKs). Activated IRAK1 recruits TNF receptor-associated factor 6 (TRAF6), which activates two ubiquitination proteins, Ubc13 and Uev1A. Ubc13 and Uev1A form a complex, and this UBC complex catalyzes the formation of a lysine 63-linked polyubiquitin chain. Ubiqutinated TRAF6 activates a complex of TGFβ activating kinase 1 (TAK1) and associated proteins, TAB1, TAB2, and TAB3, to directly phosphorylate the IκB kinase (IKK) complex. The activated IKK complex, composed of IKKα,

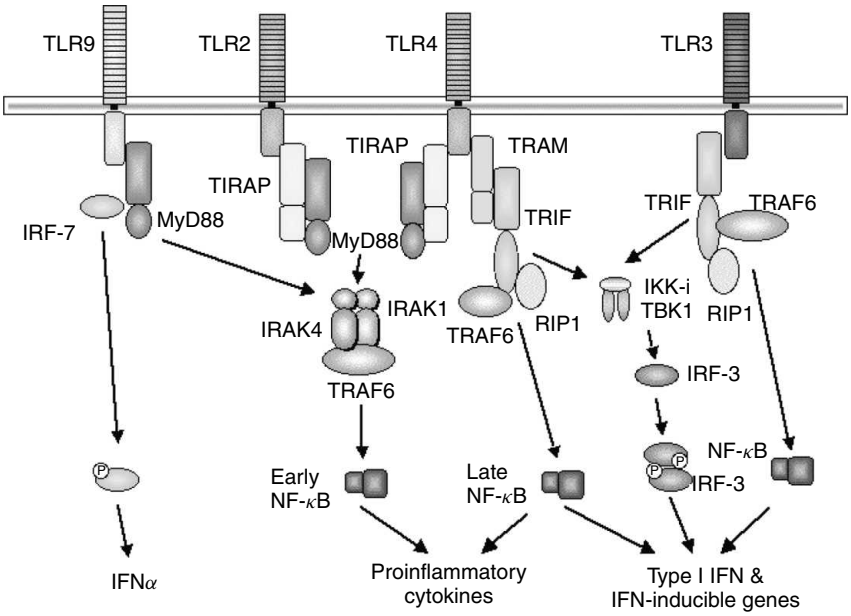

Fig. 3 The signaling pathways emanated from TLRs. Ligand binding with TLRs except TLR3 recruits MyD88 to the cytoplasmic TIR domain. MyD88, in turn, associates with IRAK4 and IRAK1. IRAK1 then activates TRAF6 leading to the nuclear translocation of NF-κB. Activated NF-κB upregulates transcription of proinflammatory cytokine genes. Another TIR-domain adaptor molecule, TIRF, is recruited to TLR3 and TLR4. TRIF activates late NF-κB via RIP1 and TBK1/IKK-i to induce phosphorylation of IRF-3. Subsequently, IRF3 homodimerizes, translocates to the nucleus and upregulates transcription of type I IFNs and IFN-inducible genes. TIRAP is specifically involved in a TLR2- and TLR4-mediated signaling pathway via MyD88, but is dispensable for the activation of TRIF-dependent pathway. TRAM bridges TLR4 and TRIF to activate TRIF-dependent pathway. TLR9 signaling is dependent on MyD88. MyD88 directly associates with IRF7 in pDC to induce phosphorylation. IRF7 subsequently activate IFNα gene expression.

IKKβ, and NF-κB essential modulator (NEMO), phosphorylates IκB, leading to its proteasome-mediated degradation, and the released NF-κB translocates from the cytosol to the nucleus to mediate the expression of proinflammatory cytokines. Next, we focus on the signaling molecules that act adjacent to the receptors, and act on the TIR domain-containing adaptors in particular.

5.1 TIR Domain-containing Adaptor Molecules

All IL-1R and TLR family members possess a TIR domain, a motif of ~160 amino acids, in their cytoplasmic region, which is critical for emanating downstream signaling pathways. Following ligand binding, TLRs dimerize and recruit cytoplasmic adaptors that also contain a TIR domain. Five TIR domain-containing adaptor molecules have been identified in mammals to date, namely, myeloid differentiation factor 88 (MyD88), TIR domain-containing adaptor inducing IFNβ (TRIF)/TIR domain-containing adaptor molecule-1 (TICAM-1), TIR domain-containing adaptor protein (TIRAP)/MyD88 adaptor like (MAL), TRIF-related adaptor molecule (TRAM)/TICAM-2 and sterile α and HEAT-Armadillo motifs (SARM). Individual TLRs can activate distinct signaling pathways through recruiting distinct adaptor molecules.

5.1.1 MyD88

MyD88 is an adaptor molecule consisting of an N-terminal DD and a C-terminal TIR domain. All IL-1R/TLR family members, except for TLR3, share at least one common signaling pathway via MyD88. After ligand stimulation, TLR/IL-1R interacts with MyD88 via the TIR domains, and MyD88 then recruits and associates with IRAK proteins by homophilic interaction via the DD. Analysis of MyD88$^{-/-}$ mice revealed that MyD88 is a gateway for signaling through all the TLR/IL-1R family members, except for TLR3. Cells derived from MyD88$^{-/-}$ mice failed to produce proinflammatory cytokines in response to various TLR ligands, such as bacterial lipoprotein, PGN, LPS, flagellin, ssRNA and CpG-DNA, in addition to IL-1β and IL-18. MyD88$^{-/-}$ cells showed defective activation of NF-κB and MAP kinases in response to TLR ligands, except for the TLR4 ligand (LPS) and TLR3 ligand (poly I:C). When MyD88$^{-/-}$ cells were stimulated with LPS, delayed activation of NF-κB and MAP kinases was observed. The defect in TLR signaling renders MyD88$^{-/-}$ mice highly susceptible to infections with various pathogens, including bacteria, fungi, viruses, and parasites, such as *S. aureus*, *Mycobacterium tuberculosis*, *Mycobacterium avium*, *Listeria monocytogenes*, Group B *Streptococcus*, *B. burgdorferi*, *C. albicans* and *T. cruzi*. Taken together, these observations indicate that MyD88 is essential for host defense against various pathogens by activating innate immune responses.

5.1.2 TRIF/TICAM-1

TRIF contains a TIR domain, a TRAF6 binding motif, and a C-terminal receptor interacting protein (RIP) homotypic interaction domain. Overexpression of TRIF activated an NF-κB-dependent reporter gene, and also activated the IFNβ reporter much more strongly than other TIR domain-containing adaptors. TRIF can associate with TRAF6 through its TRAF6 binding motif, and also interact with RIP1 via the RIP homotypic interaction motif. TRIF can also associate with TBK1, a kinase known to phosphorylate IRF3 to

induce IFNβ gene induction. Poly(I:C)-mediated NF-κB activation was abolished in RIP$^{-/-}$ cells, indicating that RIP is essential for TLR3-mediated NF-κB activation. TRIF$^{-/-}$ mice were defective in TLR3- and TLR4-mediated proinflammatory cytokine production and the IFN response. Although LPS-mediated initial activation of NF-κB occurred in TRIF$^{-/-}$ cells, it was attenuated more rapidly than that in wild-type cells. LPS-induced signaling pathways were not activated in the absence of both MyD88 and TRIF, indicating that LPS signaling is entirely dependent on these two adaptors. Overexpression of TRIF in cells induced apoptosis via caspase-8 activation, suggesting a role for TRIF in bacteria-induced cell death. Interestingly, neither TLR7- and TLR9-mediated cytokine production nor the IFN response was impaired in TRIF$^{-/-}$ cells, indicating that the function of TRIF is limited to TLR3 and TLR4 signaling.

5.1.3 TIRAP/Mal

TIRAP/Mal was cloned as another TIR domain-containing adaptor molecule from a database search. Although TIRAP/Mal was initially implicated in an MyD88-independent signaling pathway based on *in vitro* studies, generation of TIRAP/Mal$^{-/-}$ mice revealed that TIRAP/Mal was required for an MyD88-dependent pathway emanating from TLR2 and TLR4 but not for MyD88-independent pathway.

5.1.4 TRAM/TICAM-2

TRAM/TICAM-2 is a 235-amino acids protein with a C-terminal TIR domain. Like TRIF, expression of TRAM/TICAM-2 activates IRF-3 and NF-κB-dependent gene induction. In TRAM/TICAM-2$^{-/-}$ cells, LPS-induced cytokine and IFN-inducible gene expression was severely impaired. Furthermore, TRAM/TICAM-2$^{-/-}$ cells failed to sustain LPS-induced NF-κB activation compared to wild-type cells. In contrast, there were no defects in the poly I:C and CpG-DNA responses. TRAM/TICAM-2 can physically interact with both TLR4 and TRIF/TICAM-1, whereas no direct association between TLR4 and TRIF/TICAM-1 was detected. When taken together, TRAM/TICAM-2 functions to bridge TLR4 and TRIF/TICAM-1 to activate the downstream signaling pathway.

5.1.5 Sterile α and HEAT-Armadillo Motifs (SARM)

SARM is a 690-amino acid protein containing a TIR domain, two sterile α-motif (SAM) domains and an Armadillo repeat motif (ARM). SARM is evolutionally conserved from *C. elegans* and *D. melanogaster*. *C. elegans* only contains two genes that encode TIR-domain proteins. One is *tol-1*, a Toll homolog, and the other is *tir-1*, a SARM homolog. *Caenorhabditis elegans* SARM is required for resistance to microbial pathogens. However, overexpression of human SARM in mammalian cells was not sufficient to activate NF-κB and IRF3. The establishment of SARM$^{-/-}$ mice has not yet been reported.

5.2 The IRAK Family

Four IRAK family members including IRAK1, IRAK2, IRAK4, and IRAK-M have been identified in mammals, and are composed of an N-terminal DD and a subsequent serine/threonine kinase domain. While IRAK1 and IRAK4 have bona fide kinase activity, IRAK2 and IRAK-M are both inactive due to mutation of a critical residue in their kinase domains. After ligand stimulation with IL-1R/TLR, IRAK4 is

recruited to TLR/IL-1R via the DD to interact with MyD88 or TIRAP/Mal. Subsequently, IRAK4 can associate and directly phosphorylate IRAK1, which triggers the transient recruitment of TRAF6. Studies using IRAK4$^{-/-}$ mice revealed that IRAK4 is essential for activation of the IL-1R/TLR-induced signaling pathway. In contrast, although embryonic fibroblasts (MEFs) derived from IRAK1$^{-/-}$ mice exhibited an attenuated response to stimulation with IL-1β, LPS or other PAMPs, significant cytokine production was observed. This may be due to compensation by IRAK2. It is interesting to explore whether the kinase activity of IRAKs is critical for signaling, since kinase-deficient IRAK1 was still able to restore IL-1β-mediated NF-κB activation in IRAK1-deficient HEK293 cells. The role of kinase activity of IRAK4 is still controversial. Some reports showed that expression of kinase-deficient IRAK4 strongly impaired IL-1-mediated NF-κB activation, while a report showed that a kinase-inactive mutant of IRAK4 partially restored IL-1β-mediated IL-6 production as well as NF-κB activation in IRAK4$^{-/-}$ cells. Future studies will clarify the roles of the kinase activities of IRAK family members. IRAK2 also interacts with MyD88 and TIRAP/Mal, and may mediate the TIRAP/Mal signaling pathway emanating from TLR2 and TLR4. A future IRAK2 knockout study will be necessary to reveal its exact physiological functions. IRAK-M expression is restricted to monocytes/macrophages and is upregulated upon stimulation with TLR ligands. IRAK-M$^{-/-}$ mice showed enhanced production of proinflammatory cytokines in response to TLR ligands. IRAK-M perturbs the association of the IRAK4-IRAK1 complex resulting in the prevention of IRAK1-IRAK4 complex, suggesting that IRAK-M is a negative regulator of TLR signaling pathways.

These observations suggest that IRAKs play distinct roles in IL-1R/TLR signaling. IRAK4 acts upstream for IRAK1, IRAK2 can signal with TIRAP/Mal, and IRAK-M is a negative regulator of the signaling pathway.

5.3 TNF Receptor-associated Factor 6 (TRAF6)

TRAF6 belongs to a TRAF family, which is characterized by an N-terminal RING finger domain and a conserved C-terminal TRAF-domain. The RING finger domain is also found in a large family of E3 ubiquitin ligases, and TRAF6 was recently shown to function as an ubiquitin ligase, along with an E2 ligase complex consisting of Ubc13 and Uev1A/Mms2, to catalyze the formation of a polyubiquitin chain through lysine-63 (K63) of ubiquitin. TRAF6$^{-/-}$ mice exhibited severe osteopetrosis due to a defect in osteoclast differentiation. B cells and fibroblasts from TRAF6$^{-/-}$ mice showed defective responses to IL-1β, TLR ligands, and CD40 ligation. However, LPS-induced IFN-inducible gene expression was not impaired in TRAF6$^{-/-}$ cells, suggesting that TRAF6 is dispensable for the MyD88-independent pathway.

5.4 TAK1 and TAB1, TAB2 and TAB3

TAK1 was originally identified as a TGFβ-activated kinase and subsequently reported to be involved in the IL-1β signaling pathway. Ubiquitin-dependent activation of TAK1 results in phosphorylation of IKKβ and MKK6 leading to NF-κB and MAP kinase activation. Knockdown of TAK1 abolished the IKK activation induced by TNFα and IL-1β stimulation.

TAB1 and TAB2 were identified as adaptor proteins that associate with TAK1. TAB3, a TAB2 homolog, is also involved in IL-1β-mediated NF-κB and MAP kinase activation. TAB2 and TAB3 bind preferentially to lysine-63-linked polyubiquitin chains through a zinc finger domain. However, IL-1β-mediated activation of NF-κB and MAP kinases was not impaired in MEFs from TAB2$^{-/-}$ mice. TAB2 and TAB3 may therefore compensate for each other's functions *in vivo*.

6 Intracellular Recognition of PAMPs

TLRs have a transmembrane domain and are localized on the plasma membrane, ER and lysosome membrane, suggesting that TLRs are not suitable for recognizing pathogens invaded into the cytosol of cells. Various pathogens such as intracellular bacteria and viruses are supposed to be detected by PRRs in the cytosol. In mammals, the NOD-LRR family is thought to play a role in detecting cytosolic pathogens. The members of this family share a tripartite domain structure consisting of a C-terminal LRR motifs, a central nucleotide-binding oligomerization domain (NOD), and N-terminal protein–protein interaction motifs, such as caspase recruitment domains (CARDs), pyrin domains, or a TIR domain. NOD1 and NOD2, containing N-terminal CARD domains have been extensively studied for their ligands. NOD1 detects γ-D-glutamyl-meso diaminopimelic acid (iE-DAP) found in gram-negative bacterial peptidoglycan. NOD1$^{-/-}$ macrophages fail to produce cytokines in response to iE-DAP. In contrast, NOD2 is a receptor for muramyl-dipeptide (MDP) derived from bacterial PGN (Fig. 4). A missense point mutation in the human *Nod2* gene is correlated with susceptibility to Crohn's disease, an inflammatory bowel disease. A recent study revealed that NOD2 functioned to suppress TLR2-mediated activation of NF-κB in response to PGN. NOD2$^{-/-}$ mice showed enhanced IL-12 production in response to PGN stimulation, which may explain the mechanism by which NOD2 controls the susceptibility to the disease. In addition, a mutation in the NOD domain of NOD2 is the cause of Blau disease, an autosomal dominant disorder characterized by granulomatous arthritis, uveitis, and skin rash. Ligand binding of NOD1 and NOD2 causes their oligomerization and results in the activation of NF-κB through recruitment of a serine/threonine kinase, RIP2/RICK. NODs associate with RIP2/RICK through their CARD domains by a homophilic interaction. Although the number of the NOD-LRR family members is growing, the functions of members other than NOD1 and NOD2 have yet to be clarified.

Viral dsRNA is synthesized in infected cells for the viral replication. Viral dsRNA is a virus-specific molecular structure to be recognized by hosts. Most cells infected with virus produce type I IFNs in a TLR3 independent manner, implying that the mechanism recognizing dsRNA in cytoplasm plays an important role in IFN response. Cytoplasmic proteins, protein kinase R (PKR), and retinoic acid inducible protein-I (RIG-I) are implicated in viral dsRNA recognition. PKR belongs to a protein family containing dsRNA-binding domains, and is induced in response to stimulation with IFNs. Activation of PKR results in growth arrest of the cells via phosphorylating eIF2α. Several reports have shown that virus-induced type I IFN production is modestly impaired in PKR$^{-/-}$ mice. In addition, PKR$^{-/-}$ mice show defective induction of apoptosis

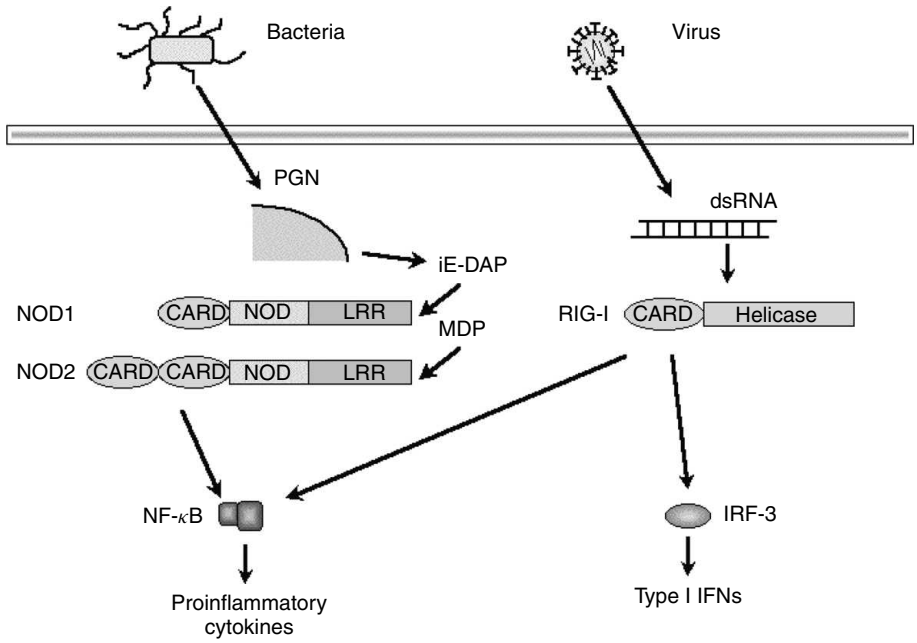

Fig. 4 Cytoplasmic recognition of microorganism. Intracellular bacteria are recognized by NOD-LRR family members in the cytoplasm. Components of PGN, iE-DAP, and MDP, are recognized by NOD1 and NOD2, respectively. NOD1 and NOD2 are composed of C-terminal LRR, central NOD domain, and N-terminal CARD domain. They detect bacterial components via LRR motifs and signal through CARD domain to activate NF-κB. When RNA viruses invade into a cell, dsRNA is generated for viral replication. RIG-I detects viral dsRNA via its helicase domain. CARD domain of RIG-I is required for activating IRF3 and NF-κB.

in response to poly I:C and bacterial burden. The other candidate of dsRNA recognition molecules, RIG-I, is also an IFN-inducible protein. RIG-I contains an N-terminal CARD domain and a DExD/H box RNA helicase domain. RIG-I interacts with poly I:C, and overexpression of RIG-I in cells conferred Newcastle Disease virus (NDV)- and dsRNA-mediated IFN response (Fig. 4). Knockdown of RIG-I by RNA interference abolished the IFN response upon NDV infection, suggesting that RIG-I is responsible for detecting RNA viruses in the cytosol of cells. It will be interesting to explore the relationships between cytoplasmic and extracellular virus recognition in host defense.

7 Pathways Activating IFN Response

Type I IFNs mainly consist of IFNα and IFNβ. The IFNα family is encoded by a cluster of multiple genes, whereas there is only a single *IFNβ* gene. Type I IFNs are strongly induced upon viral infection and stimulation with TLR ligands. Among the TLR ligands, stimulation with the TLR3, TLR4, TLR7, and TLR9 ligands, but not the TLR2 ligand, is known to upregulate type I IFN production.

Recent studies have revealed the involvement of two IKK-related kinases, inducible IκB kinase (IKK-I; also known as IKKε) and TRAF-family member-associated

NF-κB activator (TANK) TANK-binding kinase 1 (TBK1 also known as T2K), in IFN production upon TLR stimulation and viral infection. IKK-i and TBK1 can directly phosphorylate IRF3 and IRF7 *in vitro* and activate the IFNβ promoter. TBK1$^{-/-}$, but not IKK-i$^{-/-}$, MEFs showed severely impaired induction of IFNβ and IFN-inducible genes in response to LPS, intracellular introduction of poly I:C and RNA virus infection. Activation of IRF3, but not NF-κB, in response to LPS and poly(I:C) was also diminished in TBK1$^{-/-}$ cells. IKK-i/TBK1 double-deficient MEFs failed to express any detectable levels of IFNβ and IFN-inducible genes in response to poly I:C, indicating that both IKK-i and TBK1 contribute to the IFN pathway. Furthermore, these observations suggest that the signaling pathways triggered by TLR stimulation as well as cytoplasmic viral recognition converge at the level of TBK1/IKK-i (Fig. 3).

The transcription factors, IRF3 and IRF7 are essential for the expression of type I IFNs in response to viral infection and TLR stimulation. Phosphorylated IRF3 forms homodimers that translocate into the nucleus and bind to the IFN-stimulated regulatory element (ISRE) present in the promoters of a set of IFN-inducible genes to induce their expression. Initially, secreted type I IFNs activate their receptors in both autocrine and paracrine manners. This activates IFN-stimulated gene factor 3 (ISGF3), which consists of signal transducer and activator of transcription (STAT) 1, STAT2, and p40/IRF9 to amplify the response. IRF7 is also implicated in the production of IFNα. Cells deficient in IRF3 and IRF7 expression are defective in type I IFN production in response to viral infection. Moreover, IRF3$^{-/-}$ mice showed defective induction of IFNβ in response to LPS, indicating a critical role for IRF3 in the TLR4-induced IFN response.

Plasmacytoid DCs (pDCs) are known to be recruited to inflamed lymph nodes and produce large amounts of type I IFNs. pDCs express TLR7 and TLR9, and stimulation by their ligands induces IFNα production. Since this IFNα induction is independent of TBK1, the existence of a novel mechanism is hypothesized. It was revealed that MyD88 and TRAF6 can directly interact with IRF7, and induce its nuclear translocation and IFNα upregulation. (Fig. 3). Since IRF7 constitutively expresses only in pDCs, the interaction can explain the mechanism on how TLR7 and TLR9 signaling produce a large amount of IFNα in pDCs.

In summary, TLR3- and TLR4-induced IFN production is mediated through a TRIF-TBK1/IKK-i-IRF3 signaling pathway. In contrast, TLR7- and TLR9-induced IFNα production in pDC is mediated by direct association of MyD88 and IRF7, suggesting that type I IFN production is regulated by stimulus- and tissue-specific mechanisms.

8 Perspectives

As described above, the mammalian innate immune system comprised of three different mechanisms in the recognition of microorganisms. The lectin-complement pathway can detect microorganisms at the extracellular space to destroy them directly and/or cause their opsonization to facilitate phagocyte recognition. TLRs, located on the cell membrane, are responsible for activating innate immune cells by detecting microorganisms on the cell surface or in the lysosome. Finally, there are cytoplasmic PRRs recognizing viruses infected into cells and some intracellular

bacteria. Secreted type I IFNs have a strong antiviral activity by expressing IFN-inducible genes.

Recent extensive studies have revealed ligands of most TLRs and their signaling pathways. Although the cytoplasmic domains of TLRs resemble each other, the adaptor molecule(s) required for the signaling pathways differ depending on the TLR. However, most studies are implemented using PAMPs purified from pathogens to simplify the experimental system. Therefore, for comprehensive understanding of host–pathogen interactions, the next logical step would be to study the host immune responses against whole pathogens in addition to purified PAMPs and to analyze how the responses are modulated by the TLR system.

In contrast, studies on the cytoplasmic recognition of pathogens are just beginning. Although a gene family encoding putative PRR, NOD-LRR proteins, has been identified, the functions of the members are yet to be identified. The response to intracellular bacteria is more complex than previously expected. For example, in *L. monocytogenes* infection, the type I IFN response exacerbates the course of infection. IFNα/β R$^{-/-}$ mice as well as IRF3$^{-/-}$ mice are more resistant to *Listeria* infection compared to wild-type mice. *Listeria*-induced IFN response is activated independent of the TLR pathway, implying that the bacteria may take advantage of host cytoplasmic recognition system for improving their environment in hosts. Virus recognition by the host occurs both inside and outside of cells. Since viruses are complex and diverse, the host must develop an elaborate mechanism(s) to sense the invasion of various viruses.

Together, the innate immune system is not evoking a nonspecific response and random inflammation, but controlling a coordinated and adaptive response depending on the pathogen. Future studies will clarify the intricate pathogen–host relationship, allowing for more targeted therapeutic treatment of infection via modulating the innate immune system.

Bibliography 57
Books and Reviews 57
Primary Literature 58

Keywords

Apoptosis
A cell-death sequence that is largely genetically programmed.

Atherogenesis
The complex array of pathologic processes that result in the development of the atherosclerotic plaques, lesions responsible for the most common type of occlusion arterial diseases.

β-cells
The endocrine cell type in the pancreas that specializes in the secretion of insulin in response to ambient glucose concentrations and other signals.

Dyslipidemia
Altered blood levels of various lipoprotein fractions when compared with normal subjects.

Insulin Resistance
A reduced cellular response of any tissue to the binding of insulin to its cell surface insulin receptors. At the whole organism level, insulin resistance impairs insulin-induced glucose uptake by the tissues, a major predisposing factor to elevated blood glucose.

Insulin Signaling
The binding of insulin to its receptors results in a sequence of biochemical alterations, primarily phosphorylation, of a series of downstream intracellular signaling molecules, which eventually leads to the target cellular events, for example, translocation of the glucose transporter, GLUT4, induction of target gene transcription, etc.

Knockout Mice
Genetically engineered mice with a gene or a selected segment of DNA being disrupted structurally; a powerful mouse model to study the functional importance of the segment of DNA being disrupted.

Lipodystrophy
A clinical condition of either complete or partial loss of fat depot. Many specific syndromes are genetically determined, but it can also be drug-induced, most notably those caused by protease inhibitors commonly used for the treatment of AIDS.

Lipotoxicity
Dysfunction of nonadipose tissues as a result of fat accumulation.

Diabetes mellitus, a chronic progressive metabolic disorder of glucose homeostasis, is a major cause of morbidity and mortality. It is broadly categorized into type 1 and type 2, each with distinctly different pathogenesis. Diabetes mellitus is extremely prevalent, with type 2 making up nearly 90% of the cases and the incidence continues to increase at an alarming rate, in parallel with aging and the increasing prevalence of obesity worldwide. Although the pathogenesis of these two major categories is different, they share similar long-term complications as a result of inadequate glycemic control. It is well established that poor glycemic control is the major causative factor in the development of microvascular complications, affecting primarily the kidney, eyes, and peripheral nerves. Recent data suggest that hyperglycemia also plays a critical role in the development of macrovascular complications. To date, a complete normalization of glucose metabolic disturbances in diabetes remains an elusive goal. Even excellent glycemic control evades a large number of affected subjects. However, advances in our understanding of the pathogenesis of the disorder at cellular and molecular levels over the past several decades had led to significant improvements in treatment outcomes.

Insulin resistance is highly prevalent, and particularly so in Western societies. It can be found in a number of metabolic disorders, including the metabolic syndrome, impaired glucose tolerance, and in its extreme form, type 2 diabetes. In the current paradigm, insulin resistance plays a central role in the predisposition of an individual to the development of type 2 diabetes. Initially, compensatory overproduction of insulin by pancreatic β-cells enables an individual to sustain normal blood glucose levels. Over time, progressive β-cell dysfunction and loss of cell mass leads to relative insulin deficiency and diabetes ensues. Obesity not only directly causes insulin resistance, but also contributes to the progressive failure of β-cells through a number of mechanisms, including free fatty acid–induced β-cell apoptosis. Such maladaptive responses are also associated with an increased ectopic deposition of fat to nonadipose tissues, in turn, aggravating the preexisting insulin resistance.

The development of clinical diabetes is a result of combined genetic susceptibility and environmental stressors. With only a handful of exceptions, diabetes is a polygenic disorder. Identification of candidate genes may provide a more refined framework for either better understanding of the pathophysiological processes and/or for identifying novel targets for pharmacological interventions.

1 Introduction

Diabetes mellitus is a chronic progressive disease caused by inherited and/or acquired deficiency in the production of insulin, or by the ineffectiveness of the insulin produced, resulting in elevated blood glucose levels. Diabetes is broadly categorized as type 1, in which the pancreas fails to produce insulin, and type 2, in which the body fails to respond properly to the action of insulin. Diabetes is extremely prevalent. Recent data suggest

that approximately 150 million people worldwide have diabetes mellitus and amongst them, approximately 90% have type 2. This number will increase to at least 300 million by 2025 (WHO 2003). Much of this increase will occur in developing countries due to aging, unhealthy lifestyle, and the increasing epidemic of obesity, all predisposing factors for type 2 diabetes. Although the two types of diabetes differ fundamentally in their pathogenesis, they share common features in the clinical complications including those directly attributable to chronic hyperglycemia. With regard to pathogenesis, this review will focus on insulin resistance, the cardinal pathogenic factor for the development of type 2 diabetes mellitus.

Insulin resistance of the peripheral tissue predates the development of frank diabetes. This has been documented in a variety of conditions, including obesity, as well as in individuals with impaired fasting glucose. To maintain glucose homeostasis, the pancreatic β-cells overproduce insulin, leading to hyperinsulinemia. As the disease progresses, β-cell decompensation develops and frank diabetes ensues.

1.1 Gene–Environment Interactions

Type 2 diabetes is increasingly being recognized as a polygenic disorder. Nevertheless, environmental factors are considered responsible for the alarming rise in diabetes incidence in all age groups including the young since no major change in the gene pool has occurred. Furthermore, the success of intervention trials in preventing the progression to diabetes in vulnerable populations by reducing the glycemic load through acarbose (Study to Prevent Non-Insulin-Dependent Diabetes Mellitus, or STOP-NIDDM trial) or modest lifestyle change of low saturated fat weight-loss diets with regular exercise (Finnish Diabetes Prevention Study and the US Diabetic Prevention Program) has emphasized the role of environmental factors, especially when combined. Current thinking on the genesis of diabetes links genes and environment through insulin resistance. A progression is seen where insulin resistance increases over time, promoted by adiposity, especially intra-abdominal fat. Insulin levels rise and then decline over time as blood glucose levels rise due to pancreatic insufficiency. Genetic factors influencing insulin resistance, body fat distribution and β-cell failure are obviously key factors in this scenario. Interestingly, more than 80% of subjects with diabetes are obese. Observational studies support the notion that diet high in glycemic load increases the risk of development of type 2 diabetes, whereas a high fiber diet reduces the risk. Current data also support the notion that the quality of dietary fat significantly influences the development of insulin resistance and diabetes. Physical activities also confer beneficial effects on insulin resistance and improvement of glycemic control. A single bout of aerobic exercise can significantly reduce plasma glucose levels. Likewise, endurance exercise training also improves insulin resistance and glycemic control.

From the genetic standpoint, the age-adjusted increase in diabetes and obesity in the last 100 years in western nations cannot be attributed to a change in the gene pool. Rather, it is likely, in large measure, to be related to changes in diet and lifestyle. From the evolutionary perspective, our genetic makeup is ill-adapted to life in the twenty-first century. Such a lifestyle is typified by lack of need to exercise and a continuous abundance of food.

Furthermore, the nature of the food has changed. For example, traditional starchy foods that are digested more slowly, such as beans, peas, lentils, pumpernickel breads, and parboiled rice, have been replaced in the modern diet by white bread, potatoes, and glutinous white rice that tend to taste sweeter due to salivary amylolytic digestion in the mouth. As a result, lower glycemic index foods have tended to be exchanged for higher glycemic index foods. This dietary change has been even more marked in traditional cultures where contemporary carbohydrate foods have replaced very low glycemic index traditional foods in the diets, Pima Indians and Australian Aborigines of the groups that have seen some of the greatest increases in diabetes incidence. The thrifty genome has therefore been challenged by twenty-first century lifestyles. Much of the difficulty in this situation of identifying the single gene or group of genes responsible is due to the fact that the whole genome evolved to deal with a radically different lifestyle. The genetic cause of our present epidemic is therefore polygenic.

2
Peripheral Insulin Resistance

Clearance of blood glucose by target tissues is mediated by a family of facilitative transporters (GLUTs). While genes for 11 GLUT isoforms have been identified, only 7 have been shown to transport sugars (GLUTs 1–5, 8, 9). GLUT1 is expressed in erythrocytes and in vascular endothelial cells in the brain, whereas GLUT3 is expressed in neurons. GLUT1 and GLUT3 act in concert to mediate glucose uptake past the blood–brain barrier into the neurons. GLUT2 is expressed widely in a number of tissues including liver, intestine, kidney, and pancreatic β-cells. These transporters participate as part of the glucose sensing system in the β-cells and as the transport system in the intestinal cells for the absorption of dietary glucose. GLUT5 is a fructose transporter, GLUT8 appears to be important in blastocyst development, and GLUT9 is expressed in the brain and leukocytes. GLUT4, found predominantly in skeletal muscle and adipose tissues, is quantitatively the most important insulin-mediated transporter in the clearance of blood glucose. Insulin-mediated rapid cell surface translocation of the preformed and intracellularly sequestered GLUT4 remains the most investigated hypothesis for the mechanism of how insulin mobilizes glucose uptake.

2.1
Insulin Signaling

The binding of insulin to its heterotetrameric receptor (Fig. 1) results in intracellular autophosphorylation of the β-subunit and increases tyrosine kinase activity. These activated insulin receptors modulate the activities of their target effector proteins through phosphorylating a number of proximal intermediate proteins including members of the insulin receptor substrate family (IRS1-4), Shc, Cbl, and so on. An important example of this sequential activation is the tyrosine phosphorylation of IRS proteins resulting in the availability of docking sites of p85, the regulatory subunit of the type 1A phosphatidylinositol 3-kinase (PI3K). PI3K has long been recognized to play a critical role in mediating insulin-stimulated GLUT4 translocation. Activation of PI3K leads to the formation of 3′ phosphoinositide, which in turn, sequentially phosphorylates and activates phophoinositidyl-dependent protein kinase (PDK1) and PKB (also

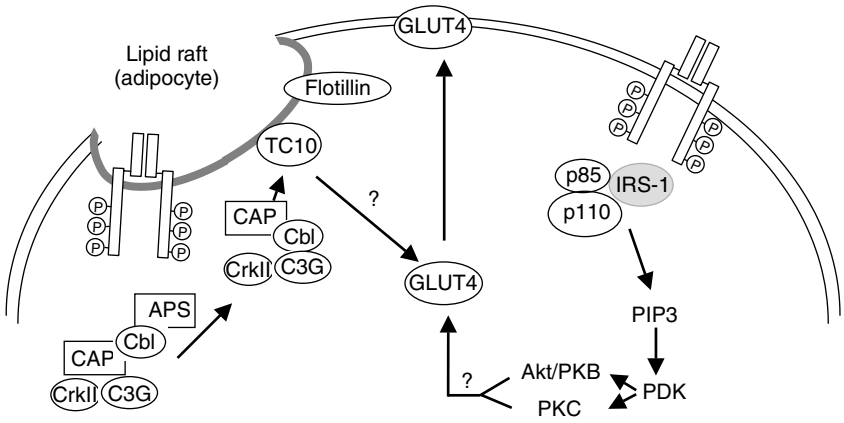

Fig. 1 Signaling cascades in insulin receptor mediated GLUT4 translocation – cross talk between IRS-mediated pathways and lipid raft-associated pathways.

known as Akt). In addition, protein kinase Cζ (PKCζ) has also been shown to participate in insulin-stimulated GLUT4 translocation. However, data to date have not identified a dominant role for either pathway.

Several lines of evidence strongly suggest that activation of PI3K in the generation of phosphatidylinositol 3,4,5-triphosphate is necessary but not sufficient for mediating the insulin-stimulated GLUT4 translocation. Novel insights recently developed were built on the observations of the comparative studies on the proximal insulin receptor tyrosine–phosphorylated substrates. It was found that in adipocytes, only insulin can induce tyrosine phosphorylation of Cbl. Two accessory proteins, APS and Cbl-associated adaptor protein (CAP), appear to act in concert. The former probably enables the insulin receptor to tyrosine phosophorylate Cbl and the latter, through its ability to interact with the caveolar protein flotillin, recruits the complex to the lipid raft in adipocytes. During this process, a small adaptor protein CrkII is also recruited to the lipid raft through its association with the phosphorylated Cbl. CrkII, in turn, interacts with the guanylnucleotide exchange factor, C3G, through one of the two tandem SH3 domains. Putting it together, insulin induces tyrosine phosphorylation of Cbl and recruits the APS/Cbl/CAP/CrkII/C3G complex to the lipid raft at the plasma membrane. Subsequent screens for small GTP binding proteins lead to the discovery of TC10, a member of the Rho family, which is instrumental in the mediation of insulin-induced, PI3K-independent stimulation of GLUT4 translocation. It therefore appears that the TC10 pathway functions in parallel with PI3K to stimulate fully GLUT4 translocation in response to insulin and these two major components are spatially separated and distinctly compartmentalized. The discovery of this novel lipid raft–associated pathway has provided a new framework for unraveling the complexity of insulin-mediated GLUT4 translocation.

2.2 Exercise and Glucose Uptake by Skeletal Muscle

Glucose can also be taken up by skeletal muscles by a number of factors

independent of insulin, including muscle contractions, hypoxia, nitric oxide, and bradykinin. Increased GLUT4 translocation has been demonstrated in mediating the increased glucose uptake for each of the above factors. In spite of its great therapeutic potential, the cellular and molecular signaling mechanism of the contraction-induced glucose uptake by skeletal muscles remains to be fully elucidated. Many candidates, including glycogen, adenosine, nitric oxide (NO), PKC, and 5′ AMP-activated protein kinase (AMPK) have been studied.

It has been shown that glycogen content of skeletal muscle modulates glucose uptake during contractions. Physiologically, glycogen-store depletion after exercise requires repletion to restore contractile functions. If carbohydrate supplementation is inadequate after exercise, glycogen is stored only incompletely. On the other hand, with the availability of carbohydrates, the restoration mechanism may indeed result in supercompensated state, rebuilding glycogen levels to beyond that of the resting levels. Studies showed that surface membrane GLUT4 protein content after contraction was inversely related to the initial glycogen levels in fast-twitch fibres. This modulator effect of glycogen has also been reported in humans. These authors reported a near doubling of plasma glucose clearance rate during one hour of exercise at 70% of maximum oxygen consumption when muscle glycogen content was 185 μmol gm^{-1} versus 800 μmol gm^{-1}. On the contrary, the stimulatory effect of insulin on glucose transport/GLUT4 recruitment was decreased when glycogen was supercompensated. The mechanism behind acute enhanced insulin action after a bout of exercise remains poorly understood. Three to four hours post exercise (when most of the acute effects of exercise ought to have subsided), insulin's effects on glucose uptake and glycogen synthase activity are increased but there was no evidence of increase in insulin-signaling intermediaries. It was suggested that this acute effect of insulin post exercise might be mediated by pathways downstream of Akt and glycogen synthase kinase 3 (GSK3). In isolated muscles, inhibition of protein synthesis with cycloheximide did not prevent muscle contraction–induced increases in insulin sensitivity, suggestive of a protein synthesis independent pathway. The molecular mechanisms underlying the modulatory effects of glycogen on insulin action are not known. Current *in vivo* data point to the possibilities of (1) increased insulin-induced activation of Akt and (2) increased AMPK activities in association with a low glycogen content. However, it is intriguing to note that glycogen depletion is not a necessary condition to observe AMPK activation with 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) and further research is required to elucidate the precise role of glycogen in postexercise insulin action.

2.2.1 Skeletal Muscle Insulin Resistance in Diabetics

It has been well established that skeletal muscle is the major site of insulin-stimulated glucose uptake in the whole body glucose homeostasis. *In vivo* studies consistently showed significant impairment in postprandial insulin mediated glucose uptake in both type 2 diabetic patients and in glucose tolerant first-degree relatives. Tracer studies further localized the defect to the nonoxidative pathways for glucose metabolism. *Ex vivo* assays quantifying insulin-stimulated glucose uptake on abdominal muscle surgical biopsy specimens were developed to show a

marked impairment in glucose transport in morbidly obese patients with or without diabetes. In concordance with this finding, muscle biopsy specimens similarly obtained from lean to moderately obese type 2 diabetic subjects revealed a significant reduction in insulin-stimulated transport of 3-O-methylglucose, a non-metabolizable glucose analog, at both physiological and pharmacological concentrations of insulin. Similar defects in insulin-mediated glucose transport have also been reported in rodent models of insulin resistance. The defects of glucose transport observed in diabetics on the basis of *in vitro* and *ex vivo* studies correlate exceedingly well with those of *in vivo* analyses.

In recent years, the technique of open biopsy of the vastus lateralis muscle under local anesthetics has made *ex vivo* specimens more assessable, and therefore, has permitted more systematic analyses. Using an exofacial *bis*-mannose photolabelling technique, Lund et al. were able to show that insulin stimulation of the muscle strip leads to an increase in the cell surface GLUT4 protein level. Since this surface level of GLUT4 is strongly correlated with the 3-O-methylglucose uptake and because of the fact that the GLUT4 turnover rate is not affected by insulin, it is concluded that the major mechanism of glucose transport in human skeletal muscle is GLUT4 translocation to the plasma membrane.

In type 2 diabetic individuals, insulin resistance is not generally associated with a reduction in skeletal muscle GLUT4 levels, but the insulin-induced translocation of GLUT4 is markedly impaired. In insulin-resistant subjects, insulin stimulation of muscle IRS-1 tyrosine phosphorylation and of IRS-1 immunoprecipitable PI3K activity is significantly less compared to insulin-sensitive controls. A reduction in insulin-stimulated Akt/PKB kinase activity in skeletal muscle from insulin-resistant type 2 diabetic individuals has also been reported, albeit not consistently. The role of Akt signaling in the impairment of glucose transport seen in type 2 diabetic individuals remains unclear. There have been a number of reports showing a reduction in insulin-stimulated glycogen synthase activity in diabetic subjects. Insulin-stimulated mitogen-activated protein kinase (MAPK) phosphorylation is not significantly altered in muscles from type 2 diabetic individuals. It appears that skeletal muscle insulin resistance in type 2 diabetic individuals is largely a result of defects in the proximal insulin-signaling steps. Interestingly, a survey of the literature on rodent models of insulin resistance, especially those data based on Zucker *fa/fa* rats, yielded remarkably similar conclusions regarding the molecular defects in mediating the insulin-stimulated glucose transport.

2.2.2 Exercise as Therapeutic Intervention in Insulin Resistance

Although our current state of knowledge in the impact of exercise on glucose homeostasis at the molecular level remains to be fully explored, many lines of evidence point to exercise as a highly desirable form of intervention in the treatment and/or prevention of type 2 diabetes among susceptible individuals. The most compelling evidence comes from the published results on the Diabetes Prevention Program trial and the Finnish Diabetes Prevention Study. Rigorous lifestyle changes, including a minimum of 150 min of physical activity per week to achieve at least a 7% reduction in body weight remains the most efficacious way of preventing the development of type 2 diabetes in susceptible subjects.

2.2.3 Acute Exercise and Insulin Resistance

It is well established that in type 2 diabetes patients, significant glucose lowering can be achieved during an acute, single bout of physical activity. A concomitant reduction in plasma insulin level has also been observed. Mechanistic studies in both type 2 diabetic subjects and in rodent models yielded very similar conclusions. Immediately after a bout of exercise (45–60 min of cycling at 60–70% of V_{max} in the human study), Kennedy et al. reported a 74% increase in plasma membrane GLUT4 protein in vastus lateralis muscle, an improvement comparable to the postexercise increase seen in nondiabetic subjects. This improvement, on the other hand, was not related to a change in GLUT4 protein expression. Similar findings were reported by King et al. in the obese Zucker rat model. These findings are consistent with the observations that contractile-induced skeletal muscle glucose transport remains intact both in animal models of insulin resistance and in type 2 diabetic subjects.

2.2.4 Chronic Exercise and Insulin Resistance

The potential beneficial effect of endurance exercise training in glucose metabolism and insulin resistance has been extensively evaluated. To date, both rodent models and human studies yielded positive results in the effect of exercise training on glucose metabolism. In rodent models, prolonged exercise consistently results in improvement in whole body glucose tolerance, whole body glucose disposal, insulin-stimulated glucose transport, GLUT4 translocation, and GLUT4 protein expression. In insulin-resistant and type 2 diabetics, endurance exercise training leads to improvements in glucose tolerance and whole body insulin-mediated glucose disposal.

The mechanisms underlying the beneficial effects of endurance training on glucose metabolism in insulin-resistant rodent models, insulin-resistant, and type 2 diabetic subjects remain poorly understood. In obese Zucker rats, exercise training results in long-term adaptive changes including upregulation of GLUT4 protein expression, increase GLUT4 translocation, and cell surface GLUT4 after insulin stimulation. However, the impact of exercise on the insulin receptor signaling pathway is less certain. Data pertaining to the effect of exercise on skeletal muscle insulin signaling in diabetic subjects are equally sparse. A better understanding of these molecular determinants will greatly enhance our ability to develop more effective therapeutic exercise strategies to combat insulin resistance and prevent onset of type 2 diabetes.

2.3 Adipocytes, Obesity, and Insulin Resistance

It has long been well recognized that obesity is a strong risk factor for the development of insulin resistance and diabetes. Likewise, up to 80% of type 2 diabetic subjects are either overweight or obese. This strong correlation is also applicable to many genetic isolates with extraordinary high prevalence of type 2 diabetic subjects including the Pima Indians and the Sandy Lake Oji-Cree. While insulin action is key to virtually all facets of adipocyte differentiation, maturation, and physiologic functions, excess fat mass promotes insulin resistance.

2.3.1 Insulin and Adipocytes

Insulin is a key regulator of nearly all aspects of fat-cell biology including

the promotion of the differentiation of preadipocytes to adipocytes. In mature adipocytes, insulin action simultaneously promotes lipogenesis and inhibits lipolysis. Meanwhile, insulin stimulates the uptake of glucose in insulin-sensitive tissues via activation of the glucose transporter and the uptake of fatty acids from circulating triglycerides (TG) in very low density lipoproteins and chylomicrons through increasing the lipoprotein lipase activity. In addition, insulin has been known to be mitogenic to the adipose tissues as well as promoting coordinated gene expressions through transcription factors of either the sterol response element-binding protein 1 (SREBP1) variants or the forkhead protein family.

In adipocytes, insulin also acts through binding to and activating the insulin receptor with a subsequent activation of PI3K, the latter being a necessary but not a sufficient condition for the induction of the Glut transporters for glucose uptake. The non-PI3K factor in adipocyte insulin signaling remains to be fully elucidated. Previous studies implicated both the Akt/PKB pathway and the PKCλ/ζ pathway, but the exact role of each in mediating glucose transport remains controversial. As discussed earlier, the lipid raft–associated TC10 pathway is also implicated in the non-PI3K signaling. In the case of adipocytes, it is further suggested that this TC10 pathway interacts with contical actin, the adipocyte-specific unique actin cytoskeleton organization, in the modulation of GLUT4 translocation.

It has been suggested that pathways that mediate the various metabolic effects of insulin may diverge downstream of the PI3K step, providing a partial explanation for the differential sensitivity of different pathways to the action of the same ambient concentration of insulin. For example, a significantly lower concentration of insulin is adequate to inhibit adipocyte lipolysis but not sufficient to reverse the hyperglycemia through increased glucose uptake. In insulin-resistant and diabetic states, adipose tissue shares similar functional defects in insulin signaling including impaired binding of insulin to the receptors, phosphorylation of the receptors, and the downstream IRS. Meanwhile, adipose tissues also manifest tissue-specific defects that are distinct from those of skeletal muscles, including a selective reduction in IRS-1 expression resulting in the recruitment of IRS-2 as the main docking protein for PI3K. In skeletal muscles, both IRS-1 and IRS-2 protein levels are normal and the signaling defect was caused by a reduction in PI3K activity in association with both IRS-1 and -2.

2.3.2 Adipose Tissue in Glucose Homeostasis and Energy Storage

The quantitative importance of adipose tissue in the regulation glucose disposal has been continuously revised. On the basis of earlier metabolic studies, it has been held that insulin-mediated glucose uptake by adipose tissue, at least in lean individuals, is relatively insignificant when compared with skeletal muscle. More recent studies in humans as well as in transgenic animal models seem to suggest the contrary. Selective overexpression of the *GLUT4* gene in adipose tissue resulted in a significant increase in whole body insulin sensitivity. A selective disruption of the *GLUT4* gene in adipose tissue led to a degree of insulin resistance comparable to that seen in the skeletal muscle-specific *glut4* knockout mice.

In humans, treatment with the $\beta 3$ selective agonist CL316,243 increases glucose uptake selectively in fat, which is also associated with an increase in whole body

glucose uptake and suppression of hepatic glucose production. While these observations collectively attest to the possibility that direct insulin-mediated uptake of glucose by adipose tissue may parallel that of skeletal muscle quantitatively, one needs to allow for contributions of other nondirect mediators.

Adipose tissue has long been viewed as a major energy depot. Excess energy intake is stored in adipocytes in the form of TGs. Insulin is a key activator of not only the action of lipoprotein lipase in the uptake of lipoprotein-derived fatty acids but also inhibits the activity of hormone-sensitive lipase to prevent lipolysis. In addition, insulin also acts directly on the insulin-responsive sterol response element–binding protein 1 (*SREBP1*) gene whose gene products, SREBP1a and SREBP1c serve as transcription factors in regulating the expressions of a series of genes including those involved in promoting endogenous lipogenesis. Insulin-deficient and insulin-resistant states including obesity are associated with enhanced lipolysis of the adipose tissue, resulting in an elevated level of circulating free fatty acids (FFA). Increased adipose lipolysis may result in a variety of dysmetabolic consequences including peripheral insulin resistance, hepatic insulin resistance, increased hepatic TG overproduction, and aggravation of pancreatic β-cell insulin secretory function. More recently, elevated FFA concentration has also been shown to result in myocardial dysfunction. Collectively, this FFA-induced multiorgan dysfunction has been dubbed lipotoxicity. The unifying concept behind such otherwise unrelated organ dysfunction is that of excessive intracellular accumulation of TGs as a consequence of nutrient excess and altered energy disposal. In this paradigm, leptin action seems to be the key switch in the proper channeling of the metabolic fate of the excess FA flux commonly seen in insulin-resistant states and obesity.

2.3.3 Lipotoxicity

Caloric intake in excess of expenditure results in an increase in adiposity and associated insulin resistance and hyperinsulinemia. Insulin resistance at the adipose tissue level results in increased lipolysis but the compensatory hyperinsulinemia may impact directly on lipid metabolism in nonadipose tissues. *SREBP1*, a gene encoding a lipogenic transcription factor, remains insulin-responsive in the insulin-resistant milieu and has been shown to be upregulated in a variety of nonadipose tissues and may play an important role in endogenous lipogenesis observed in these tissues. Excess circulating FFAs are capable of entering nonadipose tissues in the body in a fatty acid binding protein independent manner. Under normal circumstances, such excess free FA is efficiently channeled to the β-oxidation pathway and the excess energy dissipated as heat. However, in the absence of leptin action (either due to leptin deficiency or leptin resistance), nonoxidative metabolism of FFAs prevail leading to tissue steatosis, an accumulation of TGs in the nonadipose tissues. There is also evidence suggesting that high levels of FFAs and their subsequent metabolism increase the consumption of antioxidants and cause oxidative damage. In the mouse model of leptin deficiency (*ob/ob*), leptin receptor deficiency (*db/db*), and a rat model of leptin unresponsiveness (*fa/fa*), marked obesity is associated with a generalized form of steatosis, namely, significant accumulation of TG in skeletal muscle, cardiac muscle, pancreatic beta cells, kidneys, and liver. In a murine model of congenital lipodystrophy, a paucity of

adipose tissue also results in severe insulin resistance and steatosis in multiple nonadipose tissue depots. More intriguingly, the metabolic defect can be reversed by either treatment with leptin or with white fat transplantation. On the other hand, a similar transplantation experiment with white adipose without leptin fails to correct the metabolic abnormalities in another model for lipoatrophy, attesting to the critical importance of leptin in the reversal of insulin resistance and diabetes. In this particular model, a paucity of adipose tissue results in an obligate shunting of excess energy to nonadipose tissues. A concomitant lack of leptin thus promotes nonoxidative disposal of FA in nonadipose tissues, resulting in TG accumulation.

Studies on the relevance of this lipotoxicity model in humans have entered the literature. Treatment of human subjects with lipodystrophy-associated diabetes and insulin resistance with recombinant leptin has shown very encouraging beneficial effects. In the first study, 8 of the 9 lipodystrophic female subjects had diabetes, low plasma leptin levels, and fatty livers. A twice-daily leptin injection for 4 months resulted in a mean 1.9% reduction in HgA1C, a 6% reduction in fasting plasma TGs, and a 28% reduction in liver volume. In the latter study, 3 patients with severe lipodystrophy, diabetes, hepatic steatosis, and marked leptin deficiency underwent a chronic leptin-replacement regime, which resulted in a marked reversal in insulin resistance, hepatic steatosis, and hypertriglyceridemia.

2.3.4 Visceral Obesityff

Numerous lines of evidence suggest that visceral fat depots are more important in the promotion of dysmetabolic status and coronary risk than subcutaneous fat. In the Quebec Cardiovascular Study, visceral obesity was characterized by a clustering of a metabolic triad, namely, hyperinsulinemia, hyperapolipoprotein B, and small dense LDL, and was associated with a 20-fold increase in the risk of coronary heart disease over 5 years. Similar findings have also been reported in other cohorts.

Since insulin resistance and dyslipidemia are more closely associated with visceral fat mass than subcutaneous fat, a variety of biochemical and metabolic factors have been explored in explaining such differences. Visceral fat is characterized by enhanced lipolysis, resulting in an increase in FFA flux, especially into the portal circulation. Kissebah et al. showed that, *in vitro*, palmitate exposure caused a dose-dependent reduction in cell surface receptor binding of insulin in isolated hepatocytes, suggestive of a reduction in hepatic extraction of insulin. Differences in gene regulation in the different fat depots have also been reported. Collectively, these studies suggest that the deep abdominal peritoneal fat depot is less effective in insulin-mediated glucose uptake, expresses relatively less leptin, and more PPARγ. Plasminogen activator inhibitor-1 (PAI-1) is produced by adipocytes and its plasma level is strongly correlated with the degree of visceral adiposity but not subcutaneous fat in humans. Circulating PAI-1 has been implicated to play a role in thrombus formation and continues to be investigated as an emerging coronary risk factor.

2.3.5 Effect of Adipocyte Size on Insulin Resistance

Several lines of experimental evidence suggest that adipocyte size influences the impact of adipose tissues on the development of diabetes. Enlarged adipocyte size appears to be a better clinical predictor of

diabetes independent of insulin resistance. Paolisso et al. showed that the predictive value of plasma FFA concentrations on diabetes can be accounted for entirely by the adipocyte size. A large fat cell size is predictive of the development of type 2 diabetes in Pima Indians independent of age, sex, percent body fat, and fat distribution.

Though intriguing, the biological basis of such association remains speculative. Early stage obesity, secondary to overnutrition, is characterized by overrepresentation by large adipocytes (hypertrophic obesity). Such large adipocytes might be more resistant to differentiation upon further nutrient overload. As a result, continued caloric intake will progress into an accumulation of fat in nonadipose tissues including muscle, liver, and pancreatic β-cells, resulting in insulin resistance and in case of β-cells, increased apoptosis, and loss of β-cell mass ensue. Additional putative contributing factors include a disproportionally high rate of secretion of TNFα and release of FFA by the large adipocytes, aggravating insulin resistance.

Adipose differentiation is a complex, highly regulated process. The ability for a given adipose depot to recruit preadipocyte differentiation and proliferation influences the cell number and size of the fat cells. Of the various genes and hormones that regulate and modulate the fat cell differentiation machinery, three transcription factors play particularly important roles in our understanding of adipogenesis, namely, peroxisome proliferator activator receptor γ (PPARγ), CAAT enhancer binding proteins (C/EBP)s, and adducin 1 (ADD1)/SREBP1.

PPARγ, a member of the PPAR subfamily of the nuclear hormone receptor superfamily, is expressed at high levels in adipose tissue. Two splice variants, PPARγ-1 and PPARγ-2, have been identified and the former has been shown to be expressed at low levels in a variety of other tissues. This receptor is induced very early in adipocyte differentiation and has been identified as a regulator of many fat-specific genes and a *master* regulator that can trigger the entire adipogenic program. PPARγ forms heterodimers with the retinoic acid receptor α (RARα), which is recognized by the DR-1 sequence in a variety of fat-specific genes including aP2. The key regulatory role of PPARγ in adipogenesis is best exemplified by the efficient way in which *PPARγ* gene transfected fibroblasts can be induced to differentiate into adipocytes.

C/EBPα is induced relatively late in the adipocyte differentiation program. Similar to PPARγ, C/EBPα also binds to many adipose-specific genes. At a physiologic level of expression, C/EBPα is a relatively weak inducer of adipogenesis. However, when coexpressed with PPARγ, C/EBPα can become extremely potent in the induction of adipocyte differentiation.

ADD1/SREBP1 is a basic helix–loop–helix protein independently cloned as an early gene induced in adipogenesis and as a sterol response element–binding protein involved in lipogenesis. SREBP1 and its close homolog SREBP2 are products of two different genes, but the former is expressed as two splice variants SREBP1a and SREBP1c. The primary protein products of each gene are large transmembrane proteins inserted in the endoplasmic reticulum membrane in a hairpin fashion. Two sequential proteolytic steps initiated by SREBP cleavage-activating protein (SCAP) result in the release of the terminal portion of the protein into the nucleus to impart its transcriptional activity. It has been shown that ectopic expression of

SREBP1 in fibroblasts under conditions favorable for adipogenesis augment PPARγ-induced differentiation into adipocytes.

Recent studies have added new insights into the once elusive mechanism by which thiazolidenediones (TZD), a class of synthetic PPARγ ligands already approved for clinical use, ameliorate insulin resistance. Treatment of obese female *fa/fa* Zucker rats with pioglitazone for up to 28 days decreased the insulin resistant and hyperlipidemic states and caused a shift in body adiposity. In the TZD-treated rats, there was a depot-specific increase in the number of smaller fat cells due to the appearance of new fat cells and the shrinkage and/or disappearance of the existing large mature fat cells. This is consistent with the notion that treatment of rats with a PPARγ agonist might have induced the formation of new small adipocytes that may have better lipid storage capacity as well as being more insulin-sensitive, leading to a lower lipolytic activity. These changes may in turn result in a reduction in ectopic, nonadipose TG accumulation. In the case of the skeletal muscles, this may result in a significant degree of improvement in skeletal muscle insulin sensitivity. In humans, adipocyte restructuring after treatment with a TZD (troglitazone or pioglitazone) was shown to increase total body adiposity, but there was a shift from visceral fat to the subcutaneous fat in conjunction with a reduction in insulin resistance. In this case, it appears that an increase in adipose tissue mass after treatment with a TZD due to a redistribution from the large visceral fat to the smaller subcutaneous fat may be critical in the amelioration of insulin resistance.

2.3.6 Adipose Tissue as Endocrine Organ

Recent studies in adipocyte biology have expanded our conventional view of adipose tissue being primarily a fat depot for storage of energy in the form of TGs. In this traditional paradigm, insulin action on the adipocytes plays the key role of stimulating glucose uptake and lipogenesis and simultaneously inhibits lipolysis, promoting fat storage. Defects in fuel partitioning including increased adipose mass and/or increased lipolysis with increased circulating free fatty acids would result in insulin resistance, dyslipidemia, and β-cell dysfunction. We have now accrued increasing evidence that adipose tissues are programmed to secrete a large variety of substances that may act as signaling molecules in a hormonal, paracrine, and/or autocrine fashion. The secretory factors identified to date span a large variety including enzymes (lipoprotein lipase and adipsin), cytokines (tumor necrosis factor α (TNFα), interleukin 6 (IL6)), hormones (adiponectin, leptin, resistin, acylation stimulation protein, and corticosteroids), growth factors (vascular endothelial growth factor), and thrombogenesis modulators (plasminogen activator inhibitor-1 (PAI-1)). These substances are differentially regulated and are functionally diverse. Amongst them, leptin, adiponectin, TNFα, and resistin are most studied for their roles in energy homeostasis, insulin signaling, and glucose/lipid metabolism. The rapid pace of new research findings in this area does not permit an updated discussion within the scope of this paper. Readers are referred to more updated research papers and reviews.

2.3.7 Leptin

The leptin gene was first cloned when the *circulating factor* in the obese *ob*/*ob* mice was sought. The gene product, leptin, is a 16-kDa protein synthesized and secreted mainly by the white adipose tissue. The *ob*/*ob* mice, now known to

be leptin deficient, develop severe hyperphagia, reduced metabolic rate, massive obesity, and a variety of endocrinal abnormalities including infertility. Leptin acts through binding with the leptin receptor in the central nervous system with its main function in regulating food intake. Defective leptin receptors have been identified as the cause of obesity, insulin resistance, and diabetes in the *db*/*db* mice. In humans, monogenic causes of leptin deficiency–related obesity have been described but are extremely rare. The large majority of obese humans have an elevated level of circulating leptin, suggesting that *leptin resistance* is a key metabolic defect in obesity. Not surprisingly, administration of leptin to obese humans led to minimal benefit in the reversal of excess body weight and insulin resistance. On the contrary, in the relatively uncommon cases of subjects with partial lipodystrophy, affected subjects have been found to be hypoleptinemic, and leptin treatment resulted in a reversal of the metabolic abnormalities.

The leptin receptor was first isolated from mouse choroid plexus by expression cloning. This receptor is normally expressed at high levels in hypothalamic neurons and in other cell types, including T cells and vascular endothelial cells. There are several isoforms of the leptin receptor with the long form being predominantly expressed in the hypothalamus. Binding and activation of the leptin receptor results in downstream alterations of gene expression through the JAK/STAT pathway. One functional implication of this signaling is its possible linkage with the metabolic action of protein tyrosine phosphatase 1B (PTP1B). In addition to playing a role in the inactivation of insulin signaling through dephosphorylation of the insulin receptor, PTP1B also can dephosphorylate the leptin receptor–associated tyrosine kinase JAK. Leptin-deficient mice made PTP1B deficient were found to have much reduced weight gain and an increased metabolic rate, supportive of the notion that the signaling pathway cross talk is biologically significant at the whole organism level.

Leptin expression is regulated by a number of factors. Positive modulators include intracellular glucosamine (a product of glucose flux), insulin, TNFα, glucocorticoids, interleukin-1, and so on. It is intriguing to note that in cultured adipocytes, leptin mRNA expression is correlated with the lipid content and adipocyte size, but the underlying mechanism for this adaptive change remains unknown. Negative modulators include PPARγ activation, catecholamines, cAMP agonists, β-adrenergic receptor agonists, and thyroid hormones. In addition to the extensively characterized action of leptin in the regulation of energy balance, glucose homeostasis and insulin signaling, leptin has also been implicated in other biological functions, including immune activities by stimulating proliferation of T lymphocytes and in maturation of reproductive organs and in gestation. Future studies are needed to fully understand the biological function of this adipocyte-derived hormone and its role as a therapeutic in the treatment of obesity and diabetes.

2.3.8 Adiponectin (Acrp30/AdipQ)

Adiponectin was originally identified as a highly expressed gene during adipocyte differentiation. The gene was expressed exclusively by adipocytes, and the secreted protein contains an amino-terminal collagenous domain and a carboxy-terminal globular domain, the latter bearing significant homology with collagens X and VIII and complement C1q. Plasma level of adiponectin is inversely associated with

BMI in humans and is reduced in a number of murine models of insulin resistance. Furthermore, adiponectin level is lower in CHD patients compared to subjects without CHD, even after adjustment for BMI. Several lines of evidence suggest that adiponectin may have direct biological action as an insulin sensitizer by reducing hepatic glucose output as well as reducing skeletal TG content. Treatment of mice with adiponectin induced a large and sustained weight loss in a high fat/high sucrose–fed model mouse. Recent data also suggest that adiponectin confers antiatherogenic actions. Data available to date suggest the adiponectin may be a promising therapeutic candidate for the prevention of diabetes and CHD.

3 Pancreatic β-cell Dysfunction

In pancreatic β-cells, ambient fatty acids modulate the glucose-induced insulin secretion. The potency of fatty acids to promote glucose-induced insulin secretion varies with chain length and the degree of unsaturation. Acute lowering of plasma fatty acid levels is associated with a decreased insulin response to glucose. However, longer exposure of islets to FFA results in a reduction in insulin secretion in the hyperglycemic milieu. This effect of differential impact of acute versus chronic exposure of plasma FFA on insulin secretion was also observed in humans. These observations are consistent with the original Randle hypothesis based on studies in cardiac and skeletal muscle. An elevation of FFA would promote oxidation of fatty acids, which in turn inhibits pyruvate dehydrogenase activity, resulting in an accumulation of cytosolic glucose-6-phosphate with associated inhibition of hexokinase for glucose uptake. Since glycolysis is the pathway for glucose metabolism in β-cells, this FA-induced alteration in glucose uptake may play an important role in the development of β-cell secretory dysfunction.

3.1 Effect of FFA on β-cell Apoptosis

Pancreatic islets in diabetics are characterized by a reduced β-cell mass. This morphologic change is postulated to be largely a result of an accelerated β-cell apoptosis during the progression from prediabetic state to diabetes. The notion of a progressive reduction in β-cell mass caused by accelerated β-cell apoptosis as part of the natural history of the development of type 2 diabetes is supported by autopsy studies on obese and diabetic subjects when compared with lean, nondiabetic controls. Excess accumulation of TGs in β-cells, similar to many other nonadipose tissues, is a cardinal feature of the insulin-resistant state. The progressive TG accumulation has been attributed to both an elevated plasma level of FFA as substrate and a shift toward nonoxidative metabolic pathway in conjunction with an increase in endogenous lipogenesis. *In vitro* data strongly suggest that the modest increase in TG content in islets is causative of the compensatory islet cell hyperplasia and hyperinsulinemia. However, further increase in islet TG eventually leads to decompensation, triggering an accelerated apoptosis and precipitous loss of β-cell mass. In conjunction with the progression of the disease, cellular content of ceramide accumulation causes β-cell decompensation by inducing cellular apoptosis. As such, it has been suggested that FFA-induced β-cell apoptosis may, at least in part, be due to

an increased supply of substrate for the synthesis of ceramide. Inhibition of ceramide synthetase with fumonisin B1 can inhibit FFA-induced apoptosis. In parallel, increased plasma FFA is also associated with an induction of iNOS, promoting nitric oxide (NO)-induced apoptosis.

The mechanism of FFA-induced β-cell apoptosis remains incompletely understood. Recent studies suggest that the PKB pathway may play a key role. Selective transgene expression of a constitutively active form of PKB in β-cells resulted in markedly increased β-cell mass largely through preserving cell survival. This may be explained on the basis that PKB phosphorylation prevents the nuclear translocation of a number of its downstream substrates including forkhead box (Fox) transcription factors, glycogen synthase kinase-3α/β (GSK3$\alpha\beta$), bcl-2 associated death agonist (BAD), caspase 9, and murine double minute 2 (MDM2). Nuclear translocation of such factors would promote proapoptotic transactivation. *In vitro* experiments using a pancreatic β-cell line INS-1 showed that not only can FFA induce apoptosis by inhibition of PKB activation but also can inhibit the IGF-1-induced PKB phosphorylation.

Recent studies suggest that leptin can effectively protect the islet cells by promoting β-oxidative metabolism of surplus FFAs and reducing lipogenesis, especially during periods of overnutrition. Intriguingly, all fatty acids are not equally capable of inducing apoptosis. Saturated fatty acids are highly effective in the induction of apoptosis while unsaturated fatty acids are not. Human β-cell culture studies revealed that when mixing the two types of fatty acids, the unsaturated FAs are capable of preventing saturated FA-induced apoptosis.

Functional characterizations of glucagon-like peptides (GLPs) over the recent years have led to the discovery that GLP-1 may protect pancreatic β-cells from apoptosis. GLP-1 confers its biological actions through binding to the GLP1-receptor, a G-protein coupled receptor expressed in pancreatic β-cells. Not only does GLP-1 stimulate insulin secretion, it also exerts a number of other antidiabetic actions including inhibition of glucagon secretion, reduction of food intake and regulation of cell proliferation, differentiation, and apoptosis. Several lines of experimental evidence support the notion that the GLP-1 receptor is the key mediator of the antiapoptotic properties of GLP-1. In Zucker diabetic rats and in *db/db* mice, short-term infusion of GLP-1 was associated with a marked increase in β-cell mass and the development of new islet clusters. *In vivo* treatment of mice with a long-acting GLP-1 analog NN2211 and *in vivo* treatment of exendin-4, a GLP-1 receptor agonist, both led to a reduction in β-cell apoptosis. A more detailed mechanistic understanding of how GLP-1 regulates cell proliferation and apoptosis is potentially useful in the development of GLP-1 based therapeutics for the treatment or prevention of diabetes.

4 Insulin Resistance and the Liver

Hepatic glucose overproduction is a cardinal feature of type 2 diabetes mellitus. In addition, hypertriglyceridemia in association with low levels of high density lipoprotein cholesterol (HDL-C) levels, elevated levels of apolipoprotein (apo) B100, and less buoyant (small dense) low-density lipoproteins (LDL) are frequently observed

in subjects with diabetes and insulin resistance. Recent studies continue to unravel the complex underlying mechanisms both in the cause of hepatic insulin resistance and its metabolic sequelae.

An elevated blood level of FFA has been shown to promote skeletal muscle insulin resistance and β-cell dysfunction. The mechanisms by which elevated levels of FFA contribute to hepatic glucose overproduction are less well known. A recent study by Massillon et al. showed that the glucose-6-phosphatase gene can be induced by an increased level of FFA by Intralipid infusion on a background of pancreatic clamping of the FFA levels. In a somewhat more physiological model, Oakes et al. examined the effect of high-fat feeding in rats on the development of insulin resistance. Compared to chow fed rats, high fat feeding significantly impaired insulin sensitivity, resulting in hyperinsulinemia. While the compensatory increase in insulin level was able to suppress FFA release, it did not normalize the intracellular availability of FA in skeletal muscle. In the liver, glycogen synthesis was reduced because of the down regulation of glycogen synthase. Glucogenesis was enhanced in conjunction with increased FFA oxidation. However, an acute blockade of FFA oxidation with etomoxir reduced gluconeogenesis and yet, increased glucose output was unaffected. This is likely because of an alternate pathway of a sustained increase in the glucose-6-phosphatase/glucose kinase activity ratio, favoring increased glucose output. In humans, a progressive increase in FFA load through Intralipid infusion resulted in an increasing percent contribution of gluconeogenesis to the observed endogenous glucose overproduction. The relative importance of glycogenolysis and gluconeogeneis in FFA-induced hepatic glucose overproduction has been studied in healthy human subjects. Physiologically, insulin suppresses hepatic glucose output more by inhibiting glycogenolysis than by gluconeogenesis. Elevated plasma FFA levels attenuated the suppression of glucose production by interfering with insulin suppression of glycogenolysis. More recently, Lam et al. demonstrated that cell membrane translocation of PKC-δ and increased FFA oxidation may also be major contributors to the FFA-induced hepatic glucose overproduction.

FFAs have also been proposed as the link between intra-abdominal fat and peripheral insulin resistance. Obesity is associated with higher fasting plasma FFA concentrations. Intra-abdominal fat drains via the portal vein directly to the liver. At high concentrations, it has been shown to interfere with hepatic insulin binding and clearance, which even at low FFA concentrations, is only 50% efficient. It is suggested that increased insulin levels in the peripheral circulation secondary to reduced hepatic clearance downregulate peripheral glucose receptors in muscle and in the long term lead to progressive insulin resistance.

4.1 Hepatic Insulin Resistance and Dyslipidemia

Insulin resistance and diabetes are commonly associated with plasma hypertriglyceridemia, elevated apoB100, and a reduced level of HDL-C. While reduced lipoprotein lipase in the light of insulin resistance may have contributed to the accumulation of very low-density lipoproteins (VLDL) in this dyslipidemic state, a hepatic overproduction of VLDL seems to be of primary importance. Many metabolic factors influence the rate of secretion of VLDL (production rate). Since the

backbone apoB100 is constitutively synthesized in great excess and each VLDL particle contains one apoB100 molecule, the rate of apoB100 (hence VLDL) entering the circulation is governed by a number of factors in the VLDL synthetic machinery, including the translocation efficiency, lipidation of apoB with TGs, and the rate of degradation of the protein. Grossly, it appears that it is the lipids available in the ER lumen that dictate the amount of apoB eventually secreted.

Lipidation of apoB with TGs is largely mediated by the microsomal transfer protein (MTP). In addition to participating in the assembly and maturation of the VLDL particles, MTP also plays a role in stimulating apoB production through inhibition of ubiquitination, a key step in apoB degradation. Hepatic expression of MTP has been shown to be modulated by insulin through interaction of an insulin response element in its promoter. In addition, response elements to other transcription factors including adaptor protein complex (AP-1), hepatic nuclear factor 1 (HNF-1), and hepatic nuclear factor 4 (HNF-4) have also been identified. MTP mRNA expression is also regulated by hepatic sterol content and is thought to be mediated by SREBPs.

The cytosolic content of TGs, the major neutral lipid in the mature VLDL, correlates with the rate of VLDL secretion. Increased availability of cytosolic TG, either through de novo synthesis, or through esterification of FFA derived from the circulation, stimulates the VLDL production and secretion. Recently, a series of studies performed on a hamster model of insulin resistance through fructose feeding have advanced our understanding of the molecular mechanisms of insulin resistance–associated hepatic VLDL overproduction. In this model of oral fructose-induced insulin resistance, the authors observed an increase in intracellular apoB stability, and elevated levels of MTP in association with enhanced VLDL particle assembly. Impaired hepatic insulin signaling was evidenced by a reduced tyrosine phosphorylation of the insulin receptor and IRS-1. In addition, elevated protein mass and activity of PTP-1B, and a reduced level of PI3K activity were observed. The level of ER-60, a cysteine protease, was significantly reduced, consistent with the observed increase in apoB stability.

4.2 The Role of SREBP in Hepatic Insulin Resistance

SREBP1a and 1c are two variants of the same *SREBP1* gene, each using a different transcription start site. SREBP1a is a potent transcription activator of all SREBP responsive genes, including those involved in both endogenous cholesterol and fatty acid and TG synthesis. SREBP1c, on the other hand, primarily transactivates the enzymes involved in lipogenesis. In adult liver, SREBP1c is the predominant SREBP-1 isoform. The selective coordinated transduction by SREBP1c of the fatty acid program of synthesis has been demonstrated *in vivo* in a transgenic mouse model, which overexpresses the truncated version of SREBP1c that terminates prior to the membrane attachment domain. In mice, fasting markedly reduces the amount of SREBP1c in the nuclei. There is a corresponding reduction in the mRNA abundance of the SREBP1c target genes, that is, those involved in *de novo* lipogenesis. On refeeding a high carbohydrate/low fat diet, Horton et al. reported a markedly exaggerated overabundance of SREBP1c (increased 4- to 5-fold over nonfasting baseline) in association with a parallel

increase in hepatic mRNA levels of the lipogenic genes.

Recent data on a rodent model showed that the insulin-induced hepatic lipogenesis is mediated by modulating SREBP1c at the transcriptional level. By comparing two distinct murine models of severe insulin resistance, namely, the *ob/ob* (leptin-deficient) mice and the adipose-specific SREBP transgenic (lipoatrophic) mice, marked hyperinsulinemia differentially caused a significant reduction in IRS-2 mRNA but continued to stimulate SREBP1c, resulting in hepatic lipogenesis and VLDL overproduction. A more recent study further defined the role SREBP1c in the obesity–insulin resistance connection. Targeted disruption of SREBP1 in the *ob/ob* mice by cross breeding the two knockout strains selectively ameliorated the enhanced lipogenesis seen in the *ob/ob* mice without any significant alterations in fat mass and insulin resistance.

Diets rich in polyunsaturated fatty acids (PUFA) including 18 : 2 (ω-6), 20 : 5, and 22 : 6 (ω-3) have been shown to significantly lower plasma lipid levels. In a rodent model, dietary PUFA suppresses hepatic lipogenesis by reducing the nuclear content of mature SREBP1. PUFA reduces the nuclear abundance of SREBP1 by first acutely inhibiting the proteolysis of SREBP1 followed by a reduction in hepatic SREBP1 mRNA and precursor protein content. More recently, Yoshikawa et al. also showed that the suppressive effects of PUFA on SREBP1-induced lipogenesis is mediated through inhibition of the binding of the liver X receptor (LXR) to LXR response element (LRE) on the SREBP1 gene. Our understanding of the molecular mechanism of the interaction between fatty acids and transcription factors in lipid and glucose metabolism may continue to define more specific targets for treatment of hepatic insulin resistance and its associated deleterious phenotypes.

5
Insights from Gene-targeted Mouse Models

Transgenic and knockout mouse technology has provided very powerful tools for dissecting the effects of individual genes involved in insulin signaling and effector pathways. The outcomes of these studies have been extensively reviewed and will be summarized here.

5.1
Insulin Receptor (IR) Knockout Mice

The insulin receptor gene has been knocked out in mice both globally and in a tissue-specific manner. The homozygous IR knockout mice (IR−/−) appear normal at birth but rapidly develop severe metabolic phenotypes of insulin resistance at the time of suckling. These include severe hyperglycemia, ketoacidosis, hypertriglyceridemia, and steatohepatitis. Hepatic content of glycogen was reduced. Muscle was partially atrophic and the amount of adipose tissue was reduced. The mice generally died within one week of birth. On the contrary, the phenotype of the heterozygous knockout mice (IR+/−) was relatively mild. One report showed that the mice developed hyperinsulinemia at 4 to 6 months of age but only about 10% eventually developed diabetes. The insulin receptor gene has been disrupted selectively in a number of tissues, which collectively provided great insight into glucose homeostasis.

5.2
β-cell-specific IR Knockout Mice (βIRKO)

By using the cre-loxP mediated conditional gene inactivation technique, the murine IR

gene was disrupted selectively in pancreatic β-cells. The βIRKO mice were normoglycemic and began to develop significant hyperinsulinemia by 6 months of age. However, insulin secretion in response to a glucose load injected peritoneally was impaired, representing a specific impaired first-phase secretory response to glucose and not to arginine at early age. A chronic progressive impairment of glucose tolerance to an intraperitoneal glucose load was detected as early as 2 months of age. The same glucose tolerance test unmasked a reduced level of insulin levels at 4 months of age. This selective loss of first-phase secretory response is remarkably similar to the early stage of development of diabetes in humans. Furthermore, this sercretory defect was observed in spite of a quantitative preservation of β-cell GLUT2 transporter. Although it is unlikely that acute first-phase secretory defects observed in humans is caused by specific insulin receptor gene defects, these data are suggestive of β-cell insulin signaling playing an important role.

5.3 Muscle-specific IR Knockout Mice (MIRKO)

A cre-loxP system was also used to generate muscle-specific IR knockout mice. Skeletal muscle IR expression was reduced by more than 95% in conjunction with a comparable loss of insulin-stimulated IR and insulin receptor substrate-1 (IRS-1) phosphorylation. At a whole body level, these mice showed a selective increase in fat mass, plasma TG, and FFA levels, but their blood glucose levels, insulin levels, and glucose tolerance were normal.

Resting uptake of 2-deoxyglucose (2DG) by skeletal muscle is normal in the MIRKO mice. Likewise, exercise-induced 2DG uptake with and without insulin is also normal. Glycogen synthase activity is also normal in both the resting state and with exercise but not after insulin stimulation.

To further evaluate the role of muscle IR in the development of type 2 diabetes, the authors cross-bred the MIRKO into the heterozygous IR knockout mice IR+/−, and the resultant mice of interest are designated MIRKO-50%. These mice begin to develop hyperinsulinemia by 3 months. At 6 months, hyperinsulinemia becomes more severe and many animals showed hyperglycemia in a fed state.

The relatively mild glycemia phenotype in the MIRKO mice was addressed by Kim et al. In the absence of IR in skeletal muscles, there was a redistribution of the substrate to liver and adipose tissue, resulting in an expanded fat mass, hypertriglyceridemia, and elevated FFA levels, features of the prediabetes syndrome. Such intriguing findings challenge the conventional view that skeletal muscle insulin resistance is the main driving force in the development of type 2 diabetes.

5.4 Liver-specific IR Knockout Mice (LIRKO)

The liver-specific IR knockout mice develop severe insulin resistance and impaired glucose tolerance. There is a loss of inhibition of gluconeogenesis and hepatic glucose overproduction despite hyperinsulinemia, the latter was the result of a combined increase in insulin secretion and reduced clearance. The hepatic glucose overproduction seen in the LIRKO mice is also not responsive to exogenously administered insulin, bringing up the concept that hepatic glucose overproduction can continue even in the presence

of hyperglycemia in the LIRKO mice and that glucose autoregulation of hepatic glucose production does not occur in the absence of insulin signaling in liver. In this model, the severe hyperinsulinemia had led to a simultaneous differential regulation of a number of insulin-responsive genes. While phosphoenolpyruvate carboxykinase (*PEPCK*) gene expression was found to be upregulated in the LIRKO mouse, the expression of glucokinase and liver pyruvate kinase were coordinately downregulated. Likewise, the transcription of the *SREBP1c* gene continues to be positively responsive to insulin. The loss of IR in the LIRKO mouse liver results in a failure of the insulin receptor through divergent pathways that regulate gene expression, which in turn, contribute to the severe metabolic phenotypes. More interestingly, it is the analyses of these coordinated changes in gene expression that led to the identification of cis-acting DNA regulatory elements (insulin response element), which mediate insulin's effect.

5.5 Fat-specific IR Knockout Mice (FIRKO)

Fat-specific IR knockout mice were recently reported. These animals showed a sustained reduction in total fat mass and are protected from age-related glucose intolerance despite consuming higher amount of calories. There was also a reduction in total body TG content and a polarized distribution of fat cell size. In addition, these mice enjoyed a significantly prolonged life span as compared to wild-type mice. More intriguing is the observation that the phenotype of these mice is quite similar to those of calorie-restricted mice, leading the authors to suggest that it is the leanness that is the key determinant to longevity, not caloric restriction *per se*.

6 Hyperglycemic Complications

6.1 Clinical Impact – Microvascular Complications

The clinical spectrum of diabetic microvascular complications has been extensively reviewed. Two landmark clinical trials over the past decade, the Diabetes Control and Complications Trial (DCCT) for type 1 diabetic subjects and United Kingdom Prospective Diabetes Study (UKPDS) for type 2 diabetic subjects, have provided compelling evidence that hyperglycemia is the primary causative factor in the development and progression of microvascular complications, namely, retinopathy, neuropathy, and nephropathy. In these trials, excellent glycemic control has been demonstrated unequivocally to retard the progression of the microvascular complications (DCCT 1993, UKPDS 1998). Diabetic microvascular disease in retina, glomerulus, and vasa nervorum share similar pathogenic changes. At the onset of hyperglycemia, elevated intracellular glucose concentrations directly impact on vascular tone regulators, including reduced bioavailablity of nitric oxide (NO), increased production of vasoconstrictors including endothelin-1 and angiotensin II, and elaboration of permeability factors such as vascular endothelial growth factor (VEGF). Microvascular cell loss and the compensatory endothelial cell proliferation and qualitative and quantitative changes in extracellular matrix predispose to increased vascular permeability. Excessive matrix accumulation promoted

by transforming growth factor beta 1 (TGFβ1) and deposition of periodic acid Schiff (PAS) positive plasma proteins also contribute to microvascular occlusions, leading to local ischemic changes.

Our understanding of how hyperglycemia acts as the common denominator for the development of such an array of microvascular complications has recently been conceptualized by establishing a linkage between four major metabolic pathways: increased polyol pathway, increased advance glycation end-product (AGE) formation, activation of PKC, and increased hexosamine flux. A unifying hypothesis in linking these four pathways has recently been put forth. Evidence available to date suggests that the intracellular excess glucose–induced mitochondrial superoxide (O_2^-) overproduction may be the key in the simultaneous activation of all of these pathways (Fig. 2). In this hypothesis, excess mitochondrial O_{2-} production partially inhibits the glycolytic enzyme GAPDH, which in turns diverts its upstream glycolytic metabolites from glycolysis into pathways of glucose overutilization. Accumulation of cellular glucose would result in the formation of sorbitol and fructose through the polyol pathway. Excess fructose-6-phosphate is metabolized into glucosamine. Glyceraldehyde-3-phosphate in excess would provide a substrate for the increased formation of diacylglycerol for PKC activation as well as increased formation of advanced glycation end (AGE) products.

6.1.1 Intracellular Oxidative Stress

An alternate pathway by which hyperglycemia may confer oxidative stress is the overproduction of superoxide by the mitochondrial electron-transport chain. In the mitochondria, the generation of ATP is coupled to the electron-transport chain, through which molecular oxygen (O_2) may be reduced to water by electron donors NADH and $FADH_2$ from the Krebs cycle. Protons are pumped through the inner membrane of the mitochondria, sustaining an electrochemical gradient and electrons flow through intermediates

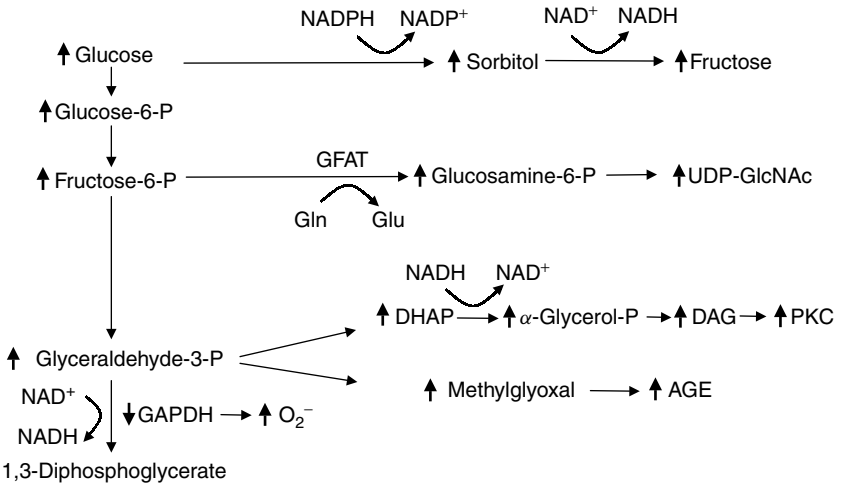

Fig. 2 Impact of elevated cellular glucose levels on multiple metabolic pathways in the promotion of diabetic complications.

such as ubisemiquinone. It has been shown that high glucose availability results in increased production of electron donors, which in turns raises the proton gradient. This, in turn, prolongs the lifetime of the electron-transport intermediates. When this number goes beyond a certain threshold, the intermediate will redirect its reactivity, greatly increasing the conversion of molecular oxygen to superoxide anion (O_2^-). This pathway of hyperglycemia-induced mitochondrial O_2^- overproduction can be attenuated by overexpression of mitochondrial superoxide dismutase (MnSOD) and uncoupling protein-1 (UCP-1).

6.1.2 The Polyol Pathway Flux

Aldose reductase is the rate-limiting enzyme mediating the reduction of glucose and other carbonyl compounds. The reduction is NADPH-dependent and has a low K_m for glucose and with elevated glucose, aldose reductase converts glucose to sorbitol, which in turn can be converted to fructose. These reactions cause simultaneous consumption of NADPH and NAD^+ respectively, leading to a reduction of cellular concentration of NADPH and increased ratio of NAD/NAD^+. A cellular depletion of NADPH would result in a reduction in the regeneration of the reduced form of glutathione (GSH), which in turn aggravates the intracellular oxidative stress. On the other hand, an increased NADH/NAD^+ ratio would inhibit the enzyme glyceraldehyde-3 phosphate dehydrogenase (GAPDH), leading to an accumulation of triose phosphate. The downstream effect of this includes an increased formation of methylglyoxal, a precursor of AGEs and diacylglycerol (DAG), the latter leading to the activation of protein kinase C (PKC).

6.1.3 Advanced Glycation End Products

Intracellular glucose at elevated concentration may also be metabolized through nonenzymatic pathways to several reactive dicarbonyls, which in turn react with amino groups of intracellular and extracellular proteins to form AGEs. Intracellular auto-oxidation of glucose leads to the formation of glyoxal. Decomposition of the Amadori product has been shown to generate 3-deoxyglucosone and fragmentation of glyceraldehyde-3-phosphate and dihydroxyacetone phosphate will form methylglyoxal. The two reactive dicarbonyls glyoxal and methylglyoxal may be detoxified by the glyoxalase system. The biological action of intracellular AGEs precursors may damage cells through a number of mechanisms. AGEs' modification of intracellular proteins results in alteration of both the structure and function of cellular proteins. AGEs' formation on extracellular matrix interferes with both matrix–matrix and cell–matrix interactions. AGEs-modified plasma proteins are capable of binding to AGEs receptors (RAGEs) on a variety of cell types including endothelial cells, mesangial cells, and macrophages. In the latter case, binding of AGEs to RAGEs in macrophages may induce production of reactive oxygen species.

6.1.4 Activation of Protein Kinase C

More than 10 isoforms of protein kinase C (PKC) have been described and nine of them are known to be activated by diacylglycerol (DAG). Elevated intracellular levels of glucose promote the *de novo* synthesis of DAG through the glycolytic intermediate dihydroxyacetone. Increased DAG primarily activates the two isoforms PKC-β and -δ, which explains the activation of a large array of downstream cellular and molecular processes responsible for the

pathogenesis of a variety of hyperglycemia-induced complications, most notably, those related to the microvascular diabetic complications.

PKC-β activation has been shown to mediate abnormal blood flow in both retinal and renal vasculatures, possibly through reduced NO production and/or an increased activity of endothelin-1, one of the most potent vasoconstrictors. In mesangial cells, PKC activation induces endothelin-1 stimulated MAP-kinase activity, which may contribute to diabetic nephropathy. PKC activation has also been invoked in hyperglycemia-induced expression of VEGF in smooth muscle cells, which may account for the observed increase in vascular permeability and angiogenesis in chronic hyperglycemia. Increased microvascular matrix accumulation in long standing hyperglycemia may also be attributable to PKC activation. The increase in PAI-1 expression in the hyperglycemic state is a predisposing factor for increased thrombogenicity and the increased NFκB activity may account for the increased expression of a wide array of proinflammatory genes. Lastly, hyperglycemia has been shown to be associated with an increased activity of the vascular NADPH oxidase system and PKC activation as a mediator has also been implicated.

6.1.5 The Hexosamine Pathway

Intracellular accumulation of fructose-6-phosphate of the glycolytic pathway may be shunted to the hexosamine pathway to produce glucosamine. The rate-limiting enzyme for this pathway, glutamine:fructose-6-phosphate amidotransferase (GFAT), converts fructose-6-phosphate to glucosamine phosphate, which will subsequently be converted to UDP-*N*-acetylglucosamine. The pathological significance of this pathway can be related to the hyperglycemia-induced upregulation of the transcription of TGF-α, TGF-β1, and PAI-1. Several lines of evidence suggest that the hexosamine-mediated transcription upregulation of *PAI-1* gene in a number of tissues including vascular cells and mesangial cells is through Sp1. Glycosylation modification of the transcription factor Sp1 may also contribute to the enhancement in its transcription activation activity. In addition to PAI-1, hyperglycemia-induced O-acetylglucosaminylation is implicated in the modulation of the activity and function of a number of other cellular proteins including eNOS modification at the Akt site and a number of PKC isoforms, promoting diabetes-related complications.

6.1.6 The Effect of Hyperglycemia on Insulin Signaling

The direct effect of hyperglycemia on insulin signaling has recently been reviewed. A 4-h incubation of rat entensor digitorum longus (EDL) muscle *ex vivo* with 25 mM glucose resulted in a 50% reduction in insulin-stimulated glucose incorporation into glycogen and a significant reduction in the insulin-stimulated phosphorylation and activation of Akt/PKB. The insulin receptor tyrosine phosphorylation, PI3K activation, and MAP-kinase activation were not affected. Furthermore, the same laboratory also demonstrated previously, both *in vivo* and *in vitro*, that acute hyperglycemia causes cellular accumulation of malonyl coA, an inhibitor of palmitoyl transferase. The resultant accumulation of palmitoyl-coA could be a source of cellular ceramide. Interestingly, incubating the EDL muscle with C2-ceramide also resulted in similar signaling defects, raising

the speculation that ceramide may play a role in mediating this signaling defect.

In cultured human vascular endothelial cells, incubation of high glucose has resulted in a reduced activation of Akt/PKB in conjunction with an increase in apoptosis, a known downstream effect of Akt/PKB. Concomitantly, cellular concentration of diacyl glyceral (DAG) and the PKC activity were both elevated.

6.1.7 The Effect of Hyperglycemia on β-cell Function

It has been well accepted that it is the development of β-cell dysfunction on the background of progressive insulin resistance that precipitates the development of frank type 2 diabetes. The early clinical defect of β-cell dysfunction, a loss of the first-phase insulin secretion in response to glucose stimulation, precedes fasting hyperglycemia by up to 5 years. Initially, hypersecretion of insulin is able to compensate for the insulin resistance, maintaining euglycemia. It is the progressive loss of β-cell mass, in part through accelerated apoptosis, and other progressive dysfunction that precipitates the decompensation, and fasting hyperglycemia ensues. Recent studies examined the potential mechanism underlying glucose-induced β-cell apoptosis. In light of the fact that β-cells have the highest level of expression of *O*-linked monosaccharide *N*-acetylglucosamine (*O*-GlcNAc) transferase (OGT), recent studies suggest that hyperglycemia may cause β-cell apoptosis through first being metabolized through the hexosamine pathway, resulting in an excessive rate of *O*-GlcNAc modification of a variety of proteins and eventually accelerated apoptosis.

Several lines of evidence suggest that hyperglycemia *per se* in turn further aggravates β-cell dysfunction as well as insulin resistance. Persistent hyperglycemia has been shown to desensitize the β-cells to glucose stimulation. The mechanisms include a reduction in the intracellular concentration of signaling molecules, for example, malonyl coA, which increases fatty acid oxidation, and desensitization of the ATP-dependent potassium channels. Meanwhile, hyperglycemia also contributes to the aggravation of peripheral insulin resistance through downregulation of the glucose transporter. This sets up a vicious cycle and the worsening of hyperglycemia will in turn aggravate β-cell function.

6.1.8 The Effect of Hyperglycemia on Oxidative Stress

Oxidant stress continues to be considered to play a critical role in atherogenesis despite the disappointing results of antioxidant trials (HOPE, BHF/MRC). Reactive oxygen species (ROS) generally consist of a number of free radicals, including superoxide anion (O_2^-) and hydroxyl radicals (OH) and their downstream reactive intermediates including peroxynitrite radicals ($ONOO^-$) and hydrogen peroxide (H_2O_2). The free radicals are highly reactive chemically and are able to initiate chain reactions. Superoxide anion radicals are generated by a number of enzyme systems in the vessel walls, including NAD(P)H oxidase, xanthine oxidase, lipoxygenase, cycloxygenase, mitochondrial oxidative phosphorylation, and so on. In defense, a family of superoxide dismutases (SOD) has evolved to transform O_2^- into hydrogen peroxide (H_2O_2). However, the H_2O_2 can, through either a Haber–Weiss reaction or the Fenton reaction, in turn lead to the formation of highly reactive hydroxide (OH^-) and hydroxyl radicals (OH). Alternatively, two endogenous defense systems, catalase and glutathione peroxidase, are able to reduce

H_2O_2. The former reduces to water and molecular oxygen and the latter, using glutathione as cosubstrate, is able to reduce H_2O_2 and lipid peroxides to water and lipid alcohols respectively. In the vessel wall, O_2^- can rapidly inactivate nitric oxide (NO) by reacting with it to produce a highly reactive species, peroxinitrite ($ONOO^-$). Therefore, O_2^- produced in excess not only provides a source for continued production of reactive oxidative species to induce tissue and lipid peroxidation, it also attenuates the potentially beneficial vasodilatory effect of NO in the vessel wall.

NAD(P)H oxidase was initially described in phagocytes as an enzyme complex capable of producing bursts of O_2^- upon stimulation for bacterial killing. The neutrophil NADH oxidase is an enzyme complex consisting of a membrane-bound cytochrome complex b558, made up of two main subunits gp91phox and p22phox and three cytosolic components, p47phox, p67phox, and rac-1. In its quiescent state, the enzyme system is inactive, but upon activation, the cytosolic components are recruited to associate with the membranous cytochrome complex. NADPH, FAD, and heme are bound to their binding sites in the gp91phox subunit and the electron transfer from NADPH to O_2 ensues, resulting in a rapid burst of O_2^- production. In recent years, nonphagocytic NAD(P)H oxidase homologs have been identified in a variety of cell types including endothelial cells, smooth muscle cells, and adventitial fibroblasts in the vessel wall. The relative abundance of each of the components in vascular cells varies with cell type. Specifically, vascular smooth muscle cells contain only trace amounts of gp91phox and p67phox. On the other hand, nox-1, a member of a family of gp91phox-like homologs, is abundant in vascular smooth muscle cells. In endothelial cells and fibroblasts, all five components are present. In both endothelial cells and smooth muscle cells, p22phox and distinct gp91phox homologs appear to be functionally important in the generation of O_2^-.

6.2 Clinical Impact – Macrovascular Complications

6.2.1 Relevance of NADPH Oxidase in Atherogenesis

Several lines of evidence suggest that NADPH oxidases play important roles in the development of atherosclerosis. First, lesion macrophage NADPH oxidase, together with 12/15 lipoxygenase and myeloperoxidase may contribute to ongoing oxidative modification of LDL, perpetuating the progression of the atherosclerotic lesion. Intracellular release of reactive oxygen species (ROS) from the NAD(P)H oxidase system may mediate the action of growth factors and cytokines, contributing to vascular hypertrophy and inflammation. Data from studies of animal models also showed consistent results. Rabbits fed on a long-term high-cholesterol diet show increased vascular O_2^- production and endothelial dysfunction. The potential role of NADPH oxidase in early atherogenesis is further supported by the observation that oscillatory shear stress, but not laminar shear stress, causes a sustained increase in NADPH oxidase–derived O_2^-. These findings may, in part, explain the propensity for atherosclerotic lesions to form at bifurcations. In addition to the flow perturbation, a number of growth factors and cytokines known to contribute to atherogenesis, including IL-6, angiotensin II, and TNF-α, have been shown to activate the NADPH oxdiases. In turn, the NADPH oxidase–derived O_2^- has been shown to

activate the downstream intracellular signaling pathways including p38MAPK (mitogenesis) and Akt/PKB (cell survival kinase) proinflammatory markers including vascular adhesion molecules and MCP-1. Vascular smooth muscle cell proliferation and migration, two important features of atherogenesis, have also been shown to be upregulated by NADPH oxidase–derived O_2^- production.

The direct effect of glucose on NADPH oxidase activity has recently been investigated. By using cultured bovine aortic smooth muscle cells and endothelial cells, Inoguchi et al. demonstrated that incubation of the cells with a high concentration of glucose for 72 h resulted in a PKC-dependent increase in superoxide production. Park et al. recently reported that high glucose concentration (25 mM) directly upregulates endothelin-1 mRNA in bovine retinal endothelial cells in a PKC-β and -δ dependent manner. In human umbilical vascular endothelial cells (HUVEC), endothelin-1 increases the production of O_2^- through upregulation of gp91phox mRNA in a dose-dependent manner and the activation is mediated mainly by the type B endothelin receptor. We recently demonstrated that a 1-h exposure of the freshly isolated C57Bl/6 mouse aorta to 30 mM of glucose increased the aortic O_2^- production by 4 fold, as determined by the lucigenin-derived chemiluminescence method.

6.2.2 The Effect of Hyperglycemia on Thrombosis

It has long been recognized that diabetes mellitus is associated with a hypercoagulable state. Patients with diabetes are significantly more prone to die of a thrombotic event. In concordance with the observed increased thrombotic event rates in diabetic patients, clinical indicators of abnormal coagulation, clotting, fibrinolytic factors, and platelet functions have been studied extensively and have been comprehensively reviewed recently. Virtually all the parameters considered have been found to be abnormal in diabetic patients. On the other hand, the relative contribution of elevated blood glucose on these abnormalities is less well studied. Limited studies are available in exploring the effect of acute hyperglycemia on healthy volunteers. It has been reported that factor VII activity, factor VIII activity, and tissue factor pathway inhibitor (TFPI) can be induced acutely through glucose infusion. Shechter et al. reported a positive correlation between glucose level and platelet-dependent thrombosis in diabetic patients with coronary heart disease.

Elevated plasma levels of plasminogen activator inhibitor type-1 (PAI-1) is one of the established markers of the metabolic syndrome. In addition, increased plasma levels of PAI-1 have also been reported in a number of acute prothrombotic states, including myocardial infarction, deep vein thrombosis, and disseminated intravascular coagulation. PAI-1 is expressed in a variety of tissues and may mediate tissue-specific thrombosis. Obese human subjects also have an elevated level of PAI-1 and the main source of circulating PAI-1 is visceral adipose tissue. In addition, *PAI-1* is also expressed in vascular endothelial cells and smooth muscle cells, and is regulated by a number of external stimuli including insulin. In insulin-resistant states, both *in vivo* and *in vitro* experiments suggest that PAI-1 gene expression continues to be responsive to insulin. Thus, glucose transport and *PAI-1* gene expression are mediated by different pathways.

Recent studies continue to support a positive relationship between elevated

glucose and PAI-1 expression. Gabriely et al. showed that hyperglycemia induces the gene expression of PAI-1 in adipose tissue and is mediated by the activation of the hexosamine pathway. Hyperglycemia has also been shown to induce *PAI-1* expression in vascular endothelial cells, which is at least mediated by the activation of the MAP kinase and PKC pathways.

6.2.3 The Effect of Hyperglycemia on Endothelial Dysfunction

The potential causative role of hyperglycemia in atherogenesis continues to draw a great deal of attention. In the UKPDS trial, Stratton et al. reported a positive association between the updated HgA1C and the incidence of the cardiovascular events. For a 1% reduction in the HgA1C, there was an associated 14% reduction in the incidence of myocardial infarction (8–21%, $p < 0.0001$). The underlying mechanism for this rather modest association remains incompletely understood. In addition to the indirect effect through increased PAI-1 levels, the potential impact of hyperglycemia on endothelial function has been extensively explored but will only be briefly reviewed here.

Endothelial dysfunction is a hallmark of atherosclerosis and may predate the appearance of atherosclerotic plaques. Several lines of evidence suggest that elevated levels of glucose directly impact on endothelial function. In a recent dog model study, Gross et al. showed that acute hyperglycemia-induced by intravenous infusion of D-glucose resulted in the development of endothelial dysfunction as assessed by coronary blood flow responses to acetylcholine, and this effect was mediated by an increased production of ROS. In a cultured endothelial cell model, exposure of bovine aortic endothelial cells to a high concentration of glucose led to a reduction in endothelial NO synthase mRNA expression and glycogen synthase activity. Elevated glucose resulted in reduction in the eNOS gene expression, glycogen synthetase activity, ERK 1,2 signaling, p38, Akt expression, and Cu/Zn superoxide-dismutase activity. Uncoupling of eNOS has also been described in diabetic subjects. Tetrahydrobiopterin (BH_4), a cofactor for endothelial nitric oxide synthase, becomes oxidized in the hyperglycemic milieu. As a result, instead of producing NO to react with O_2^- and yield $ONOO^-$, the uncoupled eNOS is capable of producing more O_2^-. Lowering the availability of BH4 in diabetics has been shown to be causative of inducing eNOS uncoupling. This reaction further results in increased production of O_2^- but a reduced availability of nitric oxide.

7 Genetic Approaches to New Genes – Candidate Genes and Susceptibility Genes

It has been well accepted that type 2 diabetes mellitus is a complex metabolic disease with strong genetic influences. Although monogenic causes of insulin resistance and diabetes such as MODY (maturity-onset diabetes of the young) have been identified, the overwhelming majority of the cases are polygenic in nature. Identification of such genes and their functional roles in the development of insulin resistance and diabetes may provide important insights for the identification of novel targets for therapeutic interventions. The candidate gene approach has been informative in identifying a number of monogenic causes of insulin resistance, albeit only accounting for a very small proportion of all type 2 diabetes. In addition,

this approach also provided insights into the role of common genetic variants of a few additional genes.

7.1 Monogenic Syndromes of Insulin Resistance and Diabetes Mellitus

7.1.1 Insulin Receptor Mutations

Over 50 different mutations in the insulin receptor gene have been described. In addition to severe insulin resistance, these affected subjects are often found to have other physical abnormalities including abnormal facies, intrauterine growth retardation, acanthosis nigricans, and so on. The phenotype of these mutations is typically transmitted in an autosomal recessive fashion, but the obligate heterozygous parents and some of the other heterozygous relatives often develop milder forms of insulin resistance comparable to those seen in type 2 diabetic subjects. Functional characterizations of these naturally occurring mutations have provided important insights into the structure–function relationships in various domains of the receptor.

7.1.2 Insulin Gene Mutations

Rare mutations in the insulin gene (*INS*) can cause hyperinsulinemia and insulin resistance. Mechanisms of impaired signaling include defective binding to the insulin receptor and changes in proinsulin leading to inefficient cleavage of proinsulin. On the other hand, a number of *INS* mutations and polymorphisms have been detected with no associated susceptibility to diabetes.

7.1.3 Familial Partial Lipodystrophy (FPLD)

Familial partial lipodystrophy (FPLD) of the Dunnigan type (also called *lipoatrophy*), is a rare form of insulin resistance associated with a characteristic form of regional loss of subcutaneous fat tissue after puberty. Other clinical phenotypes include insulin resistance, hypertriglyceridemia, glucose intolerance/diabetes, and severe hypoleptinemia. The causative defective gene was recently identified as the *LMNA*, lamin A/C gene, and the syndrome is transmitted in an autosomal dominant fashion. Several mutations of the *LMNA* gene have been identified to cause FPLD. The *LMNA* gene codes for two splice variants lamin A and C that heterodimerize, and the gene products are nuclear envelope proteins. The mechanism by which *LMNA* gene mutations cause FPLD remains unknown. In light of the remarkable similarities in the metabolic abnormalities when compared to the adipose-specific *SREBP1* transgenic mice, a murine model of generalized lipoatrophy, it has been speculated that a physical interaction between SREBP and the nuclear envelope might be essential for insulin signaling. It is of interest to note that mutations in other regions of the same *LMNA* gene can cause Emery–Dreifuss muscular dystrophy and a cardiomyopathy. In addition to mutations in *LMNA* gene, two mutations in the *PPARγ* gene have also been reported to be associated with the FPLD syndrome. Glucose transporters GLUT1, GLUT2, and GLUT4 are encoded by the *SLC2A1, SLC2A2*, and *SLC2A4* genes respectively. The *SCL2A1* gene is expressed ubiquitously in a constitutive manner but is particularly abundant in the brain. Rare mutations of the *SLC2A1* gene cause seizure disorders due to ineffective transport of glucose across the blood–brain barrier. The *SCL2A2* gene is expressed primarily in the liver and pancreas. Rare mutations of this gene have been described with the phenotype to include impaired

glucose uptake and glycogen accumulation in the liver and kidneys. *SCL2A4* encodes for GLUT4 in myocytes and adipocytes and plays a crucial role in glucose uptake by these tissues for utilization. Surprisingly, there are no single gene mutations or common polymorphisms that have been consistently demonstrated to influence diabetes susceptibility.

7.1.4 Insulin Receptor Substrates

Being located at the proximal arm of the insulin-signaling cascade, insulin receptor substrates genes (*IRS*) are natural candidates for insulin resistance and diabetes. A rare mutation in the *IRS1* gene has been detected in a subject with type 2 diabetes. On the other hand, common polymorphisms have been reported to be associated with type 2 diabetes in a number of population studies.

7.1.5 Maturity Onset Diabetes of the Young (MODY)

This is a relatively rare group of monogenic causes of early-onset type 2 diabetes (~2–5% of all type 2 diabetes cases) transmitted in an autosomal dominant manner. The affected are typically not obese and they develop diabetes as early as in childhood, but most by the third decade. All but one type of MODY, namely, MODY2, are caused by mutation of specific transcription factors and the typical primary metabolic defects are characterized by glucose-stimulated insulin secretion rather than insulin resistance. MODY2 results from mutations in the glucokinase (*GCK*) gene, encoding for glucose kinase in the glycolytic pathway. In pancreatic β-cells, a defective glycolytic pathway results in an impairment of signaling for glucose-induced insulin secretion. Genes identified to be responsible for the other MODY syndromes through either positional cloning or candidate gene approaches include a variety of transcriptional factors. Once again, defective β-cell insulin secretion is the common primary defect. Genes mutated to cause the other MODY types include hepatic nuclear factor 4α (*HNF4*α) gene in MODY1, hepatic nuclear factor 1α (*HNF*1α) gene for MODY3, insulin promoting factor 1 (*IPF1*) for MODY4, and transcription factor 2 gene (*TCF2*) for MODY5. The heterogeneity in the genes responsible for different MODY syndromes is reflected by the heterogeneity in clinical phenotypes.

Mutation in the *HNF*1α gene can cause MODY3 and represents the most commonly described MODY subtype. Hyperglycemia in MODY3 is typically severe and is frequently associated with microvascular complications. It is of interest to note that most mutations leading to MODY3 are dominant negative because mice heterozygous for the null mutation in the murine *HNF*1α gene have a normal phenotype. Data available to date suggest that only mutations located in the transactivation domain of HNF1α have a dominant negative effect.

MODY1 is caused by mutations in the transcription factor *HNF*4α, but are much less prevalent than MODY3. The mutations result in defective binding to the target DNA sequences. HNF4α is a member of the steroid/thyroid hormone receptor superfamily and an upstream regulator of HNF1α expression. Its activity is in turn modulated by a number of metabolic factors including long-chain fatty acids. The binding may result in either the activation or inhibition of HNF4α transcriptional activity as a function of chain length degree of saturation, and therefore, makes this transcription factor a

potential therapeutic target for dietary fatty acid manipulation.

A deletion mutation in the transcription factor insulin promoter factor-1 (*IPF1*) gene is found to cosegregate with a large MODY kindred. Subjects heterozygous for the mutation develop diabetes of variable severity and one homozygote for the mutated gene developed pancreatic agenesis at birth and suffered both endocrine and exocrine pancreatic deficiency. The importance of *IPF-1* in pancreatic development was confirmed by the pancreatic agenesis phenotype seen in the embryo of the *ipf-1* knockout mice.

Transcription factor 2 (TCF2)/HNF1β mutations have been described in subjects with early-onset diabetes consistent with MODY. In addition, these subjects also developed severe nondiabetic kidney disease and Mullerian aplasia.

7.2 Common Genetic Variants of Other Candidate Genes

Common variants in a number of functional candidate genes including β2- and β3-adrenergic receptor genes, PPARγ, uncoupling protein 1 gene, and so on, have been studied extensively. Two such genes, β3-adrenergic receptor (*ADRB3*) and *PPAR*γ, will be briefly reviewed here.

7.2.1 ADRB3

ADRB3 is a G-protein coupled receptor expressed largely in visceral adipose tissue. Activation by β-agonists results in cellular accumulation of cAMP that will enhance lipolysis and thermogenesis. A Trp64Arg in the *ADRB3* gene polymorphism was first discovered in Pima Indians, and homozygotes have an increased tendency to develop type 2 diabetes. A follow-up study in a Finn cohort found a positive association between this polymorphism and abdominal obesity and insulin resistance, generating further interest in exploring the potential clinical utility of this genetic variant. However, an increasing number of studies reporting negative associations dampened the pursuit of this candidate gene.

7.2.2 PPARγ

PPARγ gene encodes for two splice variants, PPARγ1 and PPARγ2. The former is expressed in a variety of tissues including muscle and adipose, but PPARγ2 is expressed virtually exclusively in adipose tissue. To date, two rare forms of dominant negative PPARγ mutations have been implicated as monogenic causes of insulin resistance and diabetes but they appear to cause lipodystrophy. Of the numerous common variants described for PARγ2, the Pro12Ala PPARγ polymorphism has received a great deal of attention. While the association between this polymorphism with diabetes and obesity has been variable, the association between this polymorphism and insulin resistance has been more consistent. Several populations of different ethnicity showed enhanced insulin sensitivity amongst those carrying the Ala12 allele.

7.3 Genome Scanning and Positional Cloning Strategies

The genome-wide linkage approach permits a systematic search throughout the genome for susceptibility genes in complex diseases such as diabetes without any prior knowledge of the functions of the genes. This technique complements the candidate gene approach because it is increasingly clear that type 2 diabetes susceptibility genes are likely to encode for

proteins of no obvious functional links to current established pathways.

Many genome scans have been reported and the results summarized in a number of recent reviews.

The *NIDDM1* locus on chromosome 2q was identified in Mexican Americans. Mahtani et al. reported a linkage at a locus near *MODY3* on chromosome 12 in Finnish families with the major phenotype being an insulin secretion defect. The identification of the calpain 10 (*CAPN10*) gene, which encodes the intracellular nonlysosomal calcium-activated cysteine protease calpain-10 as the gene involved on the *NIDDM1* locus, is a successful example of the positional cloning approach. The identification of calpain-10 holds promise in discovering novel biochemical pathways in glucose homeostasis and insulin resistance.

By using both positional cloning and a candidate gene approach, Hegele et al. have identified, in the Oj-Cree of Sandy Lake in Northern Ontario, a novel mutation in the *HNF1A* gene (*HNF1A Gly319Ser*), which is strongly linked to early-onset type 2 diabetes. The homozygotes and heterozygotes for this mutation are expected to have odd ratios of 4 and 2 in the development of type 2 diabetes, respectively. It is intriguing to observe that despite the same gene as in MODY3 being mutated, the clinical features of subjects with this *HNF1A Gly319Ser* mutation bear little resemblance to the MODY3 phenotypes.

8 Summary and Conclusions

Type 2 diabetes mellitus is an emerging epidemic worldwide, with the incidence rising in parallel with a continuing rise in the prevalence of obesity. With only a handful of exceptions, type 2 diabetes is a polygenic disorder with the clinical phenotype of insulin resistance and frank diabetes brought on by environmental factors. Treatment modalities have originally been focusing on the normalization of hyperglycemia by lifestyle modification and antidiabetic pharmacological agents, singly or in combination. More recently, rigorous lifestyle measures as well as a number of glucose lowering agents have been found to be effective in the prevention of type 2 diabetes. However, much remains to be done in our understanding of the known players in the pathogenesis of insulin resistance, β-cell dysfunction, and diabetes at the cellular and molecular levels. To significantly advance our understanding of this disorder, a multidisciplinary approach is essential.

In the area of insulin signaling, new players continue to be discovered and our understanding of the critical steps in signaling and the interactions between them and external environmental factors will prove to be informative for new therapeutic targets. The field of cross talk between specific signaling pathways and their interactions with cell membrane microdomains represent an exciting area of future research. A systematic dissection of the signaling pathways by the generation of knockout and transgenic mice will also offer novel insights into the functional roles of these individual players at the whole mammalian organism level. The genome projects will soon make available an enormous amount of DNA sequence data from various species, including humans, and will facilitate discovery of novel genes involved in insulin resistance and diabetes. Our evolving view of the adipose tissue as not just a passive fat depot

but rather as being a dynamic and active secretory organ, together with a better understanding of biological functions and how they interact with external modulating factors, will be critical for us in developing effective strategies to combat increasing adiposity and their metabolic and functional sequelae. The biological actions of adiponectin and its interactions with other adipocyte-derived hormones and cytokines appear to be an area critical to our understanding of how obesity may contribute to insulin resistance. In addition, partitioning of energy as mediated by distribution and redistribution of body fat may hold the key for our future understanding of links between obesity, insulin resistance, and diabetes and for better design of therapeutics. The discovery of glucagon-like peptides (GLPs) and their respective receptors holds great promise to effectively control hyperglycemia and to reestablish the β-cell proliferation/apoptosis balance with the ultimate goal of preserving β-cell mass.

Uncontrolled hyperglycemia continues to be the main threat for the development of microvascular disease and our currently available therapeutics frequently fail to completely normalize glycemia or to maintain control. Tracking the pathophysiology of high glucose–induced long-term diabetic microvascular complications to the function at subcellular organelle function will facilitate better preventive measures. Likewise, the role of hyperglycemia in the development of macrovascular complications continues to stimulate great interest. Current understanding of the role of elevated blood glucose, especially postprandial hyperglycemia on arterial wall function, including endothelial function, oxidative stress, and the interaction with lipoproteins, may lead to the identification of novel targets for atherogenesis in diabetes.

Keywords

Cell Transfections
This is a method whereby a biologically active protein is introduced (chemically or electrically) to cultured mammalian cells. Live cells are then assayed to determine the effects of the introduced protein. Results from such experiments may reveal how the protein behaves within the cell.

Fatty Acids
This is a long carbon chain carboxylic acid that condenses with glycerol to form fat. The carbon chain can vary in length and number and positioning of doulble bonds.

Knockout Mouse
This is a scientific model used to explore the role that a particular gene may play in humans. Within the knockout mouse, the gene of interest is removed using artifical methods; all cells within the resulting mutant mouse contain the same mutation. The appearance, biochemical characteristics, and behavior of the knockout mouse can provide some indication of the gene's normal role in the mouse.

Lipid-binding Proteins
These are small, soluble intracellular proteins capable of non–covalently binding fatty acids and other small hydrophobic ligands. It is believed to participate in lipid transport.

Lipid Transport
This is the movement of lipids from the site of synthesis to their site of utilization.

Long-chain fatty acids (FA) are required by cells as membrane phospholipid constituents, metabolic substrates, precursors for signaling molecules, and mediators of gene expression. They are in constant flux and need to enter and leave cells rapidly and, presumably, in a regulated manner. The relatively low aqueous solubility of fatty acids would strongly suggest that specific and efficient mechanisms must exist for their intracellular transport. High levels of fatty acid–binding proteins (FABPs) are found within cells, and, although it has been shown that these proteins noncovalently bind fatty acids with high affinity, their true *in vivo* functions have remained elusive. This chapter focuses on recent findings assessing the transport function of FABPs, and on data supporting putative mechanisms by which FABPs may be involved in cellular FA uptake, efflux, and intracellular transport.

1 Equilibrium Binding of Fatty Acids to FABPs

There are 12 members of the mammalian FABP family, each with specific tissue expression and, with the exception of the retinol and retinoic acid–binding proteins, each is named after the first tissue of isolation (Table 1). In the tissues where they are found, FABPs are typically expressed abundantly, at reported levels of up to 13% cytosolic protein and, as their name suggests, are capable of noncovalently binding long-chain fatty acids with high affinity and a 1 : 1 molar stoichiometry. Ileal lipid-binding protein (I-LBP) and liver fatty acid–binding protein (L-FABP) prove exceptions to this rule: both can bind more bulky, hydrophobic ligands such as lysophospholipids, bile acids, eicosanoids,

Tab. 1 Members of the family of mammalian intracellular fatty acid–binding proteins.

Name	*Occurrence*
E-FABP (K-FABP)	Epidermis, adipose, mammary tissue, tongue epithelia, testis
H-FABP	Heart muscle, cardiac and skeletal muscle, brain, mammary gland, kidney, adrenals, ovaries, testis
B-FABP	Brain, central nervous system
M-FABP	Peripheral nervous system
A-FABP	Adipose, macrophages
I-FABP	Small intestine
I-LBP	Small intestine (distal)
L-FABP	Liver, small intestine
CRABP-I	Brain, skin, testis
CRABP-II	Epidermis, adrenal
CRBP-I	Liver, kidney, testis, lung
CRBP-II	Small intestine

and some drugs, I-LBP does not bind fatty acids, and L-FABP is capable of binding two fatty acids simultaneously. A recent NMR spectroscopic study showed two distinct binding environments for these FA, and suggested that binding of the first fatty acid precedes and may facilitate binding of the second.

Equilibrium binding studies have been used in an attempt to elucidate the functional characteristics of each FABP type. Most recently, the ligand-binding specificity of eight human FABPs (heart, liver, intestine, adipocyte, myelin, epidermal, brain fatty acid–binding protein, and ileal lipid-binding protein) were directly compared by Zimmerman et al. using the Lipidex assay. By determining the equilibrium distribution of FAs between the resin and FABP, binding affinities were measured and, with the exception of I-LBP, ranged from 0.2 to 4.01 μM. The results obtained showed that the proteins have a lower affinity for palmitic acid than for oleic and arachidonic acids. Contrary to these findings and using the ADIFAB (acrylodated intestinal fatty acid–binding protein) method, Richieri and colleagues showed that human FABPs from brain, heart, intestine, liver, and myelin pertained little or no selectivity for a particular FA, and obtained K_d values ranging from 2 to 400 nM. ADIFAB consists of intestinal fatty acid–binding protein covalently modified with the fluorescent acrylodan group, which exhibits a marked red-shift in fluorescence emission maximum upon fatty acid binding, enabling unbound concentrations of FAs to be accurately measured. A further study using isothermal titration calorimetry (ITC) to determine the binding of FAs to human L-FABP yielded a stearate K_d value approximately 100 times larger (weaker binding) than that determined by Richieri et al., and concluded, again in contrast to Richieri et al., that L-FABP preferentially binds unsaturated relative to saturated FAs. It is possible, however, that the poor solubility of stearate, as well as the high fatty acid concentrations necessary for the ITC injection method, resulted in a lower stearate concentration in the reaction vessel, thus producing lower values for heat change, and therefore uncertain K_d values.

In spite of these discrepancies over absolute K_d values, it is clear from these and earlier *in vitro* binding experiments that FABPs bind long-chain saturated and unsaturated FA. Indeed, NMR and X-ray crystallographic structures of holo FABPs reveal the position of the bound FA within the individual protein structures. In some structures, including intestinal FABP (I-FABP) and adipocyte FABP (A-FABP), the fatty acid adopts a bent conformation, while in others, such as heart FABP (H-FABP), it adopts a U-shaped conformation.

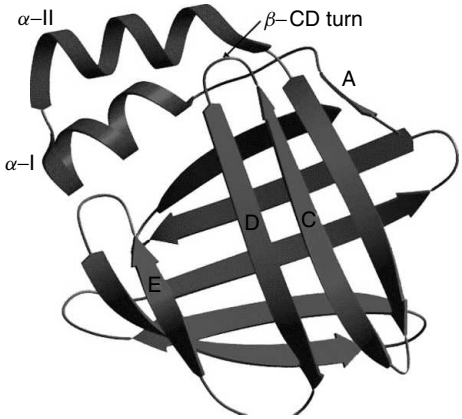

Fig. 1 The three-dimensional structure of a representative cytoplasmic fatty acid–binding protein. The protein comprises a flattened β-barrel capped by two short α-helices. The helices and closely positioned α-turns are believed to behave as a portal for ligand entry and exit.

Notwithstanding a wide variance in primary sequence, all members of the FABP family consist of a β-barrel structure capped by two α-helices; the latter is believed to behave as a portal for ligand entry and release (Fig. 1). This hypothesis was supported recently by fluorescence-based experiments comparing A-FABP and a triple mutant (V32G, F57G, K58G), designed to enlarge the putative portal opening by reducing the size of portal amino acids. By comparing analinonaphthalene sulfonic acid (ANS) and oleate-binding affinities and ANS-binding rates, it was found that enlargement of the A-FABP portal region increased ligand accessibility into the cavity with only modest effects on ligand-binding affinity, suggesting that dynamic fluctuations in this region regulate cavity access. Indeed, the solution structure of apo I-FABP was shown to exhibit a higher degree of mobility in this portal area in comparison with that of the ligand-bound I-FABP complex relative to other domains in these proteins. In an attempt to better understand the mechanism by which FAs bind to and dissociate from the binding cavities of FABPs, Richieri et al. constructed 31 single amino acid mutants within the portal region and in the region of the gap between the βD- and βE-strands of I-FABP, and determined binding affinities and rate constants for FA binding. Together with experiments examining these parameters as a function of ionic strength, it was suggested that the FA initially binds through an electrostatic interaction to Arg56 on the surface of the protein, before inserting into the binding cavity, with a reversal of these steps for the dissociation reaction.

The structural and biochemical studies of FA binding to FABPs do not directly demonstrate a ligand transport function for the proteins, however, they nevertheless, are consistent with their participation in such processes. It has been suggested that upon binding to FABP, the FAs traverse the aqueous cytoplasm in a more energetically favorable manner owing to increased aqueous solubility of FAs, in that lateral diffusion of FABP-bound FAs proceeds more rapidly than that of membrane-bound FAs.

2 *In vitro* Fatty Acid–Transfer Properties of FABPs

The mechanisms by which members of the FABP family transfer FAs to

membranes has been examined in a series of *in vitro* experiments. These studies examined the rate of anthroyloxy-labeled fatty acid (AOFA) movement from FABPs to model acceptor vesicles containing a nonexchangeable fluorescence quencher, using a fluorescence resonance energy transfer assay.

Transfer of fluorescent FA analogues from adipocyte, heart, intestinal, epidermal, brain, and myelin FABPs (A-, H-, I-, E-, B-, and M-FABPs), and of retinol from cellular retinal–binding protein I (CRBP-I), to membrane targets appears to involve collision of the holo protein with both zwitterionic and anionic membranes, with more effective collisional interactions occurring with the latter. FA transfer rates were directly proportional to acceptor membrane phospholipid concentration, and were modulated by changes in the acceptor vesicle charge, implying that FABP and membrane come into direct physical contact, with ligand transfer occurring during the collision. Further studies suggested that positively charged (lysine) residues on the protein surface are involved in this ligand transfer process and are likely to participate in the formation of effective FABP:membrane complexes that involve electrostatic interactions. Site-directed mutagenesis of A-FABP and H-FABP demonstrated that lysines in the helical cap domain are important for establishing these ionic interactions. In particular, lysine residues on αI, αII, and the βCD-turn of both proteins, and possibly the βA-strand of A-FABP, but not H-FABP, were shown to be directly involved in these charge:charge interactions. Indeed, by removing I-FABPs two α-helices, fatty acid transfer no longer occurred via a collisional mechanism. Furthermore, creation of chimeric proteins of A- and H-FABPs revealed that the αII-helix is important in determining the absolute fatty acid transfer rates, while the αI-helix appears to be particularly important in regulating protein sensitivity to the negative charge of membranes. The FABP α-helical domain, part of the same region believed to enable FA entry and exit, is therefore extremely important not only for the direct interaction with membrane phospholipids during ligand transfer to membranes but also in regulating FA transfer rates.

The direct interaction of the FABPs with membranes was further assessed using fluorescence-based assays and direct physical measurements and, as suggested by the transfer experiments, the α-helical domain and surface lysine residues therein proved particularly important for membrane association. Preincubation of anionic vesicles with I-FABP prevented the subsequent binding of the peripheral membrane protein cytochrome c, suggesting that the I-FABP was membrane-bound. In contrast, helix-less I-FABP demonstrated 80% less efficiency in preventing cytochrome c binding than intact I-FABP. Further direct support for I-FABP:membrane interactions was provided by surface pressure measurements, Brewster angle microscopy, and infrared reflection-absorption spectroscopy (IRRAS), which revealed that I-FABP interacted with 1,2-dimyristoyl phosphatidic acid monolayers to a stronger extent than its helix-less variant. IRRAS studies also showed I-FABP to induce a stronger conformational ordering of the lipid acyl chains than helix-less I-FABP. The interaction of A-FABP with vesicles was also directly measured using FTIR spectroscopy, and it was found that A-FABP interacts much more strongly with acidic than zwitterionic membranes, and that neutralization of A-FABP positive surface charges by acetylation considerably weakens its interactions with negatively

charged vesicles. As for I-FABP, these data supported observations gained from the cytochrome c–binding assay, whereby A-FABP, but not acetylated A-FABP, was able to prevent subsequent cytochrome c binding to model anionic membranes. Notably, in all these studies, the degree of membrane interaction correlated directly with the rate of fatty acid transfer, indicating that FABP: membrane interactions are functionally related to their fatty acid transport properties. While the primary mode of FABP:membrane interaction appears to involve the establishment of ion pairs between positive charges on the protein surface and negative membrane charges, recent mutagenesis studies have suggested that hydrophobic interactions between I-FABP helix II residues and membrane phospholipids may also play a role in establishing the collisional interactions that promote FA transfer. Indeed, it has been noted that those FABPs displaying a collisional mechanism for fatty acid transfer, possess a conserved, solvent-exposed, bulky hydrophobic side chain located on αII, namely, a phenylalanine, leucine, isoleucine, or methionine. L-FABP on the other hand, displaying a diffusional mechanism for fatty acid transfer, possesses a Glu in this position. The aforementioned results for I-FABP thus suggest that exposed hydrophobic residues could be involved in membrane association, thereby rendering a subsequent interaction with a receptor protein more efficient and permitting the exchange of ligand without its entry into an aqueous phase.

L-FABP and CRBP-II are the only members of the FABP family that were found not to transfer FA, or retinol in the case of CRBP-II, via a collisional mechanism. L-FABP transfers FAs to membranes almost 50-fold slower than members of the family, exhibiting a collisional FA transfer mechanism. Despite overall structural similarity, this particular FABP appears to transfer its ligand via aqueous diffusion, a mechanism that does not involve direct protein–membrane contact. In support of this mechanism, the rate of FA transfer from L-FABP to membranes was modulated by neither the concentration of acceptor membranes nor their composition; however, changes in the ionic strength of the buffer directly affected the transfer rates, indicating that the transfer rate is regulated by aqueous solubility of the fatty acid. Recently, it was demonstrated that the alpha-helical region of L-FABP is responsible for its diffusional mechanism of fatty acid transfer to membranes. This was deduced by the creation of a pair of chimeric proteins, one containing the ligand-binding domain of I-FABP and the alpha-helical region of L-FABP (alphaLbetaIFABP) and the other containing the ligand-binding pocket of L-FABP and the helical domain of I-FABP (alphaIbetaLFABP). Transfer rates from the chimeric proteins compared to those of the wild type indicated that the slower rate of FA transfer observed for L-FABP relative to that of I-FABP is, in part, determined by the helical domain of the proteins. In addition, absolute FA transfer from alphaLbetaIFABP to membranes occurred by aqueous diffusion whereas FA transfer from alphaIbetaLFABP occurred via protein–membrane collisional interactions. Like L-FABP, CRBP-II also displayed a diffusional mechanism, and indeed proved ineffective in preventing cytochrome c from binding to phospholipid vesicles. Davies et al., however, were able to observe L-FABP binding to anionic phospholipid vesicles using the fluorescent probe DAUDA, an undecanoate (11 : 0) derivative. Upon binding to FABP,

the fluorescence maximum of DAUDA becomes blue- shifted and exhibits a substantial increase in intensity. By mixing a preformed DAUDA:L-FABP complex with anionic vesicles, an immediate decrease in DAUDA fluorescence occurred, indicating a release of DAUDA from the protein. As this did not occur with zwitterionic vesicles, the results suggested that interaction of L-FABP with the anionic membrane interface induces a rapid conformational change, resulting in a reduced affinity of DAUDA for the protein. The nature of this interaction was suggested to involve both electrostatic and nonpolar forces. It is important to note, however, that these L-FABP–membrane interactions were observed at very low ionic strength assay conditions, but were not found at physiologic ionic strength.

From these experiments, it was hypothesized that those FABPs exhibiting a collisional mechanism for FA transfer are most likely to be involved in the targeted transfer of FAs, whereby the proteins interact either with specific membrane lipids and/or membrane protein domains to transfer their fatty acid ligand. Recently, it was also discovered that transfer of anthroyloxylated fatty acids (AOFAs) from phospholipid membranes to I-FABP (in the opposite direction from that initially examined) also occurs via a collisional mechanism. It is possible then that FABPs may utilize membrane–protein interactions not only for the acquisition of ligand but also for their delivery. By displaying a diffusional mechanism for fatty acid transfer whereby no direct protein–membrane interaction occurs, it is likely that L-FABP and CRBP-II may function in the capacity of cytosolic fatty acid or retinol reservoirs. Nonetheless, just as the apparent membrane interactions may be surrogates for FABP–protein interactions, the absence of apparent L-FABP or CRBP-II–membrane interactions does not preclude protein–protein interactions; however, the nature of any such interactions is likely to be different from that of the collisional FABPs.

It is important to note that much of the work examining the mechanisms of FA transfer to model membranes has involved the use of rodent FABPs. With numerous links between FABPs and several chronic diseases in humans becoming ever clearer, a direct comparison of fatty acid transfer properties of rodent and human proteins demonstrated that the rates and mechanisms of FA transfer from L-, I-, A- and H-FABPs observed for rodent proteins were the same for their human counterparts. An additional approach used to examine the transport function of the FABPs is fluorescence recovery after photobleaching (FRAP) for solution conditions. In such studies, the effective diffusion (Deff) of the fluorescent probe *N*-(7-nitro-2,1,3-benzoxadiazol-4-yl)-stearate (NBDS) is evaluated in individual cells or in so-called model cytosol. Using this approach, it has been found that the rate of NBDS movement correlates directly with the intracellular level of L-FABP in HepG2 cells and hepatocytes, the level of I-FABP in embryonic stem cells, the total FABP level (L-FABP + I-FABP) in rat enterocytes isolated from different intestinal segments, and the L-FABP concentration in solutions prepared to resemble cytosol with intracellular membranes. The mechanism for these effects likely involves FABPs acting to limit fatty acid partitioning into immobile membranes, thereby increasing the rate of movement of the fatty acid. Additionally, specific effects of FABPs in cells were also suggested by results in which permeabilized HepG2

cells were used to generate various cytosolic compositions by incubation with different protein-containing solutions; in these studies, albumin was found to be only 4-fold more effective than equal concentrations of L-FABP in increasing the Deff of NBDS, despite the fact that its fatty acid–binding capacity is of far greater magnitude greater than that of L-FABP, as is its FA-binding affinity.

3 Transfection Studies of FABP Function

To assess FABP function within a more physiological milieu, FABP genes have been transfected into model cell cultures and subsequent changes in FA uptake and metabolism examined.

A series of experiments examining L-cell fibroblasts or embryonic stem cells transfected with L-FABP and/or I-FABP appeared to suggest a role for L-FABP in cellular FA uptake; when NBDS or the fluorescent fatty acid analog *cis*-parinaric acid (cPnA) were added to cells expressing L-FABP and compared with control cells, or cells expressing I-FABP, a 2-fold increase in fluorescence intensity was observed. However, care should be taken in the interpretation of these results given that the quantum yield for cPnA binding to L-FABP differs by a similar degree to that of cPnA binding to I-FABP. Indeed, in contrast to these results, it was reported more recently that expression of L-FABP in transfected L-cell fibroblasts did not reduce the uptake of ^{3}H palmitic acid, its oxidation, or induction of lipid accumulation, although uptake of ^{3}H phytanic acid was found to be reduced. Thus, apparently similar studies provide divergent results. More recently, nevertheless, Wolfrum et al. used peroxisome proliferators to increase L-FABP levels in HepG2 cells, and antisense L-FABP to decrease L-FABP mRNA expression, and the net oleate uptake was shown to correlate directly with the L-FABP content of the cells. When I-FABP was expressed at 2-fold higher concentrations in L-cells, it was found that cPnA uptake was lower relative to cells with lesser I-FABP levels. In contrast, the decreased level of I-FABP expression in differentiated relative to undifferentiated embryonic stem cells was also correlated with a decrease in fatty acid uptake. Results of experiments involving overexpression of Ala^{54} and Thr^{54}-I-FABP (two I-FABP forms created by a single base pair alteration in the human I-FABP gene) in Caco-2 intestinal cells must also be viewed carefully. A 2-fold increase in net fatty acid uptake was obtained from Thr^{54}-I-FABP-transfected cells and approximately 5-fold more triacylglycerol was secreted into the basolateral medium relative to Ala^{54}-I-FABP-transfected cells. In differentiated cells of both lines, the endogenous levels of L-FABP were decreased relative to control cells, although L-FABP levels, nevertheless, remained 2- to 3-fold higher than levels of I-FABP. Moreover, it has subsequently been demonstrated that, in contrast to earlier indications, Caco-2 cells do in fact express I-FABP. A recent publication, nevertheless, reported that parent Caco-2 cells as well as mock-transfected cells fail to express detectable levels of I-FABP mRNA or protein at any stage of differentiation; upon transfecting cells with I-FABP, radiolabeled oleic acid was used to monitor fatty acid metabolism, and it was deduced that I-FABP expression in intestinal cells leads to reduced triacylglycerol secretion. Clearly, the precise function of I-FABP in the enterocyte remains uncertain. Given the additional variable of high levels of expression of L-FABP in this

cell type as well, an understanding of the functional properties of enterocyte FABPs, in particular, remains a challenge.

CHO cells transfected with A-FABP showed a 1.5- to 2-fold increase in the net uptake of oleate and, interestingly, expression of equivalent levels of a mutated form of A-FABP with reduced fatty acid binding failed to produce a change in uptake. In contrast, expression of A-FABP in L6 myoblasts did not alter the net fatty acid uptake, although the degree of differentiation in these cells differed from that of control cells. Recently, electroporation of A-FABP into 3T3-L1 preadipocytes was used as an alternative technique for modifying the level of cellular FABP directly. Incorporation of A-FABP was found to result in an increase in the initial rate of palmitate uptake relative to that of control cells, supporting an A-FABP-mediated transport function.

An early report suggested an increase in net fatty acid uptake in cells overexpressing H-FABP, whereas overexpression of H-FABP in L6 myoblasts was reported not to alter uptake. Expression of CRBP-I in Caco-2 cells increased net retinol uptake by about 2-fold; in this clone, a large decrease in endogenous Caco-2 expression of CRBP-II was also found. Results from experiments involving CRABPI knockout ABI cell lines suggested that CRABPI functions to regulate the intracellular concentrations of retinoic acid and to maintain high levels of oxidized retinoic acid metabolites such as 4-oxoretinoic acid within cells.

Thus, some studies have yielded conflicting results, although some have provided strong evidence for an intracellular FABP-mediated transport function. A general concern with stable transfections in cultured cell lines is that parallel alterations may be occurring due to clonal variability, and secondary changes due to the altered expression of a specific gene, in this case an FABP, may also occur. The latter issue is not as serious as the former, as it at least points to the potential involvement of the FABP in a cellular process, if not to its precise role at the molecular level. It would seem of great importance for transfection studies, especially, to demonstrate a dose-dependent functional response to FABP expression. Thus far, only the studies of Wolfrum et al. have been so rigorously performed. The use of direct protein transfer techniques, including streptolysis, electroporation, and lipid- and peptide-based protein transfer reagents, avoid entirely the issue of clonal variability, and in large part the concern about secondary changes in cellular processes. These approaches have not yet been widely applied to the FABPs.

4 Cellular Fatty Acid Transport via FABP–Protein Interactions

As noted above, *in vitro* studies suggested a potential for FABPs to act as targeting proteins, conveying their ligands to particular domains on organellar membranes, and/or to specific protein receptors. Recently, a number of protein–protein interactions involving FABPs have indeed been reported, suggesting that fatty acids may be transported around the cell in a regulated manner.

Using yeast two-hybrid assays, an interaction between A-FABP and hormone-sensitive lipase (HSL) was discovered and further confirmed with experiments including GST-pulldowns and coimmunoprecipitation of the HSL:A-FABP complex. The A-FABP interaction domain of HSL was found to reside in the N-terminal portion of the protein, whereas the catalytic domain is known to be localized to the

C-terminus. Recent studies showed that HSL residues His194 and Glu199 appear to be critical for interactions with A-FABP. Furthermore, it has been shown that A- and E-FABPs, but not I-or L-FABPs, bind to HSL in a 1 : 1 molar stoichiometry only in the presence of oleate. However, A-, E-, L-, H-, and I-FABPs all stimulated HSL activity to an equivalent and relatively modest extent, approximately two-fold. A point mutant of A-FABP which does not display FA binding did not cause this modest stimulation. These results suggest that the effect of the FABPs on HSL is likely via binding of fatty acid but that a protein–protein interaction is not required for the FABP effect. It appears then that binding and activation of HSL by FABPs are separate and distinct functions. Taken as a whole, results from these experiments suggest that A-FABP may function to traffic fatty acids away from the triglyceride droplet after hydrolysis by HSL, thereby promoting further lipolysis by diminishing end-product inhibition. It is still unclear exactly where A-FABP is taking the fatty acid. However, given the evidence of an association between H-FABP and the cytoplasmic domain of the putative transmembrane fatty acid transporter CD36/FAT in milk-fat globule membranes, as determined by gel filtration and coimmunoprecipitation, it is possible that A-FABP transports its bound fatty acid to the plasma membrane and, via an interaction with CD36/FAT, promotes the efflux of the fatty acid out of the cell (Fig. 2). Alternatively, in the adipocyte or in other cell types, an FABP could transport its bound fatty acid to internal sites for re-esterification.

Again using the yeast two-hybrid system, an interaction between L-FABP and the lipid-activated transcription factor

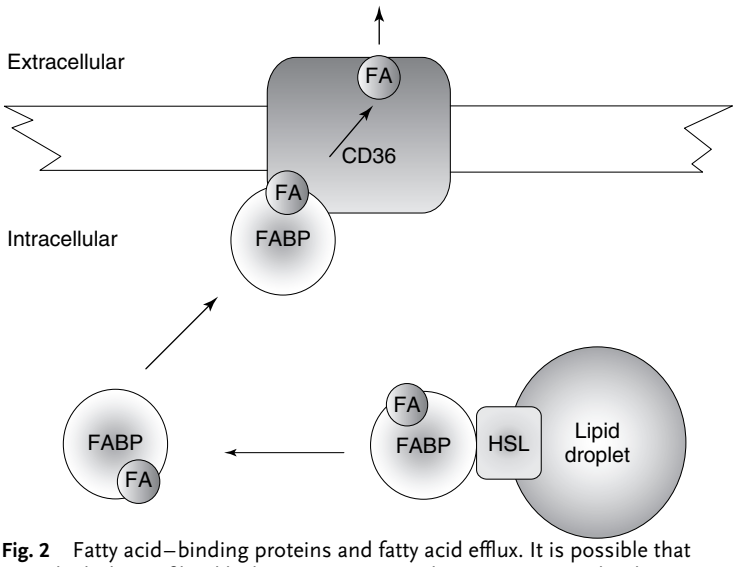

Fig. 2 Fatty acid–binding proteins and fatty acid efflux. It is possible that upon hydrolysis of lipid by hormone sensitive lipase (HSL) or other lipases, the resulting fatty acid (FA) is bound by fatty acid–binding protein (FABP) and transported through the cytoplasm to CD36/FAT, whereupon the fatty acid is off-loaded for efflux out of the cell. Adipocyte FABP-HSL and heart FABP-CD36 complexes have been identified.

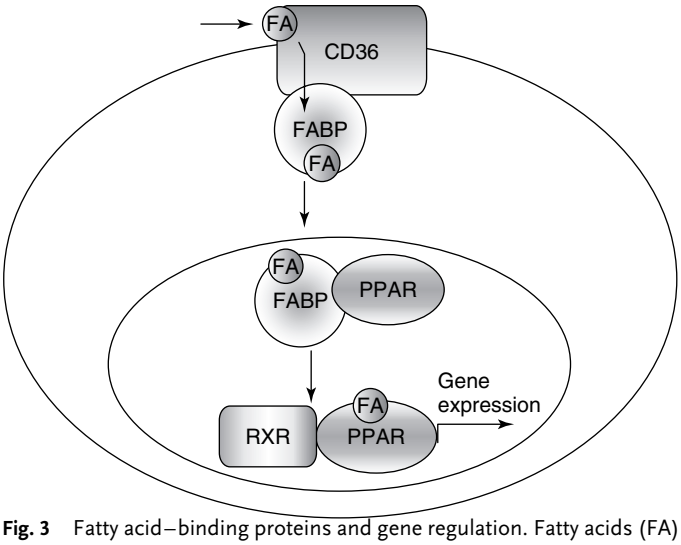

Fig. 3 Fatty acid–binding proteins and gene regulation. Fatty acids (FA) taken up by CD36/FAT may then be bound in the intracellular space by fatty acid–binding proteins (FABP) for transport through the cytoplasm to the nucleus. Upon entering the nucleus, the FABP:FA complex binds to PPAR, the FA becomes PPAR-bound, and gene expression is initiated. CD36 has been shown to play a role in fatty acid uptake, FABPCD36 complexes have been identified, and an association between liver FABP and PPARa has been shown. There is also evidence to suggest that adipocyte and epidermal FABPs may be partially localized to the nucleus.

peroxisome proliferator activated receptor α (PPARα) was found. This was further assessed by pull-down assays and immunoprecipitation, and was shown to be independent of ligand binding. PPARα is believed to be a nuclear target for fatty acids and initiates gene expression of enzymes involved in lipid metabolism. Such an association, therefore, suggests that L-FABP serves to directly traffic its fatty acid ligand, gained possibly from an interaction with CD36/FAT and/or other transmembrane transporters, to the nucleus and, thereby, directly functions in the regulation of gene expression (Fig. 3). Indeed, recent results indicate that A- and E-FABPs localize in the nuclei of 3T3-LI adipocytes as well as the cytoplasm, suggesting that these two FABPs may also exert their action at the level of the nucleus.

An interaction between the extracellular domain of CD36 and the S100A8/S100A9: arachidonic acid complex has also been identified in endothelial cells, implying a role for this protein in transcellular eicosanoid metabolism. Given that the coordinate regulation of gene expression and similar abundance of cytoplasmic FABPs and membrane FA transporters have been repeatedly demonstrated, it is highly possible that a concerted, vectorial mechanism for FA transport exists.

5 Insights into FABP Function from Null Mice

Several mouse models null for different FABPs have been created by targeted gene disruption. These are providing important support for the transport functions

of these proteins, as well as new insights into additional potential functions. Of the four FABP knockouts described thus far, the H-FABP-null mouse provides perhaps the clearest example of functional consequences. Mice lacking expression of H-FABP displayed a substantial decrease in long-chain fatty acid uptake into the heart. Further studies in cardiac myocytes isolated from wild-type and H-FABP$^{-/-}$ animals demonstrated that defective fatty acid uptake and oxidation appears to be the underlying cause of the phenotype observed in the whole animal. Interestingly, the CD36/FAT-null mouse displays a very similar FA uptake phenotype, again suggesting a concerted action by the two types of FA transport proteins in cellular FA trafficking. In the H-FABP-null animals, as well as in the CD36 nulls, physiological compensation for the decreased FA uptake appears to occur by an increase in glucose uptake and oxidation in the heart, and not by compensatory increases in other members of the FABP family. H-FABP is also expressed in the mammary gland; however, the H-FABP$^{-/-}$ mice were reported to have no overt phenotype in this tissue.

Mice null for I-FABP were also reported to show no apparent compensation with other FABPs. The I-FABP$^{-/-}$ mice developed hyperinsulinemia that was independent of body weight gain, an unusual dissociation. The I-FABP knockout mice gained more weight and had higher levels of serum triglycerides. This could indicate an involvement of the protein in lipid absorption, metabolism, or secretion, which requires further investigation. An intriguing finding in this model was that the effects on weight and serum triglycerides were observed only in male mice. This gender dependency suggests a previously unexplored interaction between I-FABP and sex hormones.

In contrast to the H-FABP and I-FABP nulls, mice null for the ap2 gene, which encodes A-FABP, showed a dramatic increase in expression of another FABP, keratinocyte FABP (K-FABP), in adipose tissue, perhaps accounting for the absence of a dramatic phenotype in the animals. Initial investigations of low fat–fed mice showed few differences between wild-type and A-FABP$^{-/-}$ animals; however, feeding a high-fat diet resulted in lower levels of plasma insulin and reduced adipocyte mRNA levels of tumor necrosis factor α (TNFα) relative to wild-type mice; the absence of hyperinsulinemia appeared to occur despite the presence of high-fat diet-induced obesity. Conversely, however, it was found that younger aP2$^{-/-}$ mice, despite maintaining lower glucose levels, did in fact develop hyperinsulinemia on a high-fat diet; the plasma insulin levels were directly correlated with the degree of adiposity in both wild-type and A-FABP$^{-/-}$ mice. Further, adipocyte TNFα secretion was not reduced relative to wild-type mice. These results indicate that a dissociation between the development of obesity and the development of hyperinsulinemia, a hallmark of obesity, is not apparent in the A-FABP$^{-/-}$ mice under all circumstances.

The aP2$^{-/-}$ mice have also been reported to have modest decreases in lipolysis in some, but not all, investigations, as well as a small increase in basal levels of *de novo* fatty acid synthesis. Interestingly, the pancreatic insulin secretory response to β-adrenergic stimulation was suppressed in aP2$^{-/-}$ mice, and when aP2 deficiency was introduced into the genetically obese ob/ob mouse, animals lacking A-FABP showed decreased pancreatic insulin secretion as well as improved glucose tolerance. Thus, despite the discrepancies and despite the fact that the mechanisms of the

null phenotypic changes are not clear, the collective results indicate that further explorations of the role of A-FABP in fatty acid flux and systemic lipid and glucose metabolism are warranted. A recent report of dramatic increases in serum levels and adipose expression of a bone morphogenic protein in the A-FABP-null mice may point to a heretofore unrecognized interaction between fatty acid metabolism and bone development. At this point, however, the nature of any such association remains to be explored.

A potentially critical involvement for A-FABP in the development of diet-induced atherosclerosis has been recently revealed by studies of A-FABP$^{-/-}$ mice crossed with mice deficient in apoE, the latter being a well-established model of dietary atherosclerosis. ApoE$^{-/-}$ animals develop severe coronary arterial occlusion on a high-fat diet; in dramatic contrast, the A-FABP$^{-/-}$ /apoE$^{-/-}$ mice developed only trivial lesions, strongly indicating a role for A-FABP in the accumulation of lipid-rich foam cells in the arterial intima. As A-FABP is highly expressed not only in adipose tissue but also in macrophages, the results suggested that it plays a critical role in the development of hypercholesterolemia-induced atherosclerosis, likely at the level of the macrophage. Indeed, recent bone marrow transplantation studies showed that macrophage-expressed A-FABP, rather than adipocyte A-FABP, was likely to be primarily involved in the development of dietary atherosclerosis. K-FABP was also found to be expressed in macrophages; however, unlike the compensatory upregulation of expression observed in adipose tissue of the ap2$^{-/-}$ mice, macrophage K-FABP expression remained unchanged. The mechanisms for the apparently proatherosclerotic effects of macrophage A-FABP do not appear to be primarily related to cholesterol ester accumulation, as this was altered to a modest extent, if at all, in macrophages from the A-FABP$^{-/-}$ /apoE$^{-/-}$ mice. Interestingly, levels of interleukin 6, interleukin 1β, macrophage inflammatory proteins 1α and 1β, and macrophage chemoattractant protein 1 were decreased in the apoE/A-FABP-deficient macrophages relative to apoE$^{-/-}$, indicating a role for A-FABP in inflammatory cytokine and chemokine expression.

Recently, the generation of a skin-type FABP (K- or E-FABP)-null mouse (E-FABP$^{-/-}$) was reported. Here, too, it appears that compensatory changes in another FABP are found: mice lacking E-FABP showed increased expression of H-FABP in skin. A dramatic phenotype was not observed in the E-FABP$^{-/-}$ mice; however, changes in the rate, although not the extent of transepidermal water loss, were observed. The mechanisms by which the FABPs may participate in the water barrier function of skin are not yet known. Recently, the construction of transgenic mice overexpressing the *FABP5* gene encoding E-FABP in adipocytes was reported. In adipocytes from FABP5 transgenic mice, the total FABPprotein level was found to increase 150% as compared to the wild type due to a 10-fold increase in the level of E-FABP and an unanticipated 2-fold downregulation of the A-FABP. These results suggested that there is a positive relationship between lipolysis and the total level of FABP, but not between lipolysis and a specific FABP type.

L-FABP knockout mice displayed a dramatically reduced cytosolic fatty acid–binding capacity in the mouse liver. Moreover, a dramatic shift in liver lipid distribution in favor of cholesterol, cholesterol esters, and phospholipids was observed. L-FABP, sterol carrier protein 2

(SCP-2) and SCP-*x* may contribute to this change in liver lipid distribution; levels of SCP-2 (a known cholesterol-binding protein) increased by approximately 75% while levels of SCP-*x* decreased in L-FABP null mice. As yet, however, the precise mechanism and functional consequences of the shift in hepatocellular lipid distribution in L-FABP null mice are unknown. It is also worth noting that in an independently generated L-FABP$^{-/-}$ mouse, no changes in SCP-2 levels were detected. In other studies the role of L-FABP in peroxisomal oxidation and metabolism of branched-chain fatty acids was investigated using cultured primary hepatocytes isolated from livers of L-FABP null and wild-type mice. L-FABP gene ablation reduced maximal, but not initial, uptake of phytanic acid (the most common branched-chain fatty acid), and inhibited phytanic acid peroxisomal oxidation and microsomal esterification. L-FABP gene-ablated hepatocytes were also found to contain decreased levels of free fatty acids and triglyceride. L-FABP null mice have been further used to test the hypothesis that L-FABP limits the availability of long-chain fatty acids for oxidation and for PPARα, a fatty acid–binding transcription factor that determines the capacity of hepatic fatty acid oxidation. Indeed, it was found that the mechanisms whereby L-FABP affects fatty acid oxidation may vary with physiological condition; under fasting conditions, hepatic L-FABP appears to contribute to hepatic LCFA oxidation and ketogenesis by a nontranscriptional mechanism, whereas L-FABP appears to activate ketogenic gene expression in fed mice. Independently of these experiments Newberry et al. generated mice with a targeted deletion of the endogenous L-FABP gene and have characterized their response to alterations in hepatic fatty acid flux following prolonged fasting. The resulting data point to an inducible defect in fatty acid utilization in fasted L-FABP null mice that involves targeting of substrate for use in triglyceride metabolism.

6 Perspectives

It has often been suggested that the expression of more than one type of FABP in a single tissue or even a single cell type, is a strong predictor that FABPs perform functions other than or in addition to bulk binding and transport. Recent studies of Widstrom et al., using displacement of the fluorescent probe ANS, showed that H-FABP can bind arachidonic and linoleic acid metabolites, which serve as components of cell signaling cascades. If the FABPs do in fact act to target as well as bind FAs, as the data reviewed here suggest, then there must be specific signals for protein trafficking. An interesting feature of A-FABP is that Phe57 on the β-CD turn rotates by more than 90° into the binding cavity of the apoprotein relative to the holoprotein. As discussed earlier, differences in apo-FABP versus holo-FABP tertiary structures are especially notable in the helix-turn-helix portal domain. Differences in the regulation of fluorescent FA transfer from I-FABP to membranes relative to transfer in the opposite direction further suggests differential trafficking properties of apo- and holo-FABPs. Thus, structural changes in apo- versus holo-FABPs might act to alter interactions with other cellular structures, prevent competition between apo- and holo-proteins for interaction with the same receptor, act as a signal for a ligand-bound protein, or change FABP affinity for a membrane. Evidently, there is much to be learned about the precise

mechanisms by which FABPs participate in the uptake, efflux, and intracellular transport and metabolism of their small hydrophobic ligands.

Books and Reviews 109
Primary Literature 109

Keywords

Allosteric
Literally ''other space.'' The action of a modifying molecule on a protein at a site other than the usual site at which the protein performs its function.

Anabolic
Those reactions in biological systems that synthesize more complex molecules from simpler molecules, usually requiring energy.

Binding Site
A cavity formed by the folding of the protein backbone with the ability to bind a specific molecule in a discrete three-dimensional relationship to the bulk of the protein structure.

Catabolism
Those reactions in biological systems that break down complex molecules to simpler molecules, usually releasing energy that is trapped and converted to ATP.

Dissociation Constant
The dissociation constant (K_d) is a measure of the equilibrium between protein-bound and unbound ligand. K_d is also the concentration of ligand that occupies half of the protein binding sites in the system. A measure of the strength of ligand binding; a smaller K_d value represents stronger binding than a larger K_d.

Enzyme
A protein synthesized by the cell that behaves as a catalyst to a chemical reaction. Almost all chemical reactions in a biological system are catalyzed by a separate and specific enzyme. Enzyme names usually end in ''-ase.''

Fatty Acids
A class of biological molecules that consist of long, hydrophobic carbon chains with a single carboxylic acid functional group; poorly soluble in water and, hence, hydrophobic.

Gluconeogenesis
The synthesis of ''new'' glucose from smaller molecules such as pyruvate. In some senses, a reverse of the results of glycolysis.

Glycation
The chemical reaction between a carbohydrate and an amine group of a protein to form a covalent C=N bond (a Schiff base). The surface structure and operation of the protein is usually altered by this reaction.

Glycolysis
The series of 10 biochemical, enzyme-catalyzed reactions that converts glucose into pyruvate and is located in the cytoplasm of the cell.

Hyperlipidemia
A concentration of lipids larger than consistent with normal levels.

Inhibition Constant
The concentration of an enzyme inhibitor that reduces the enzyme rate by one half (K_i).

Isoform
In proteins, a variant of a protein coded for by a different gene and contains one, or more, amino acid substitutions.

Isosteric
Literally, ''same space.'' The action of a modifying molecule on a protein at a site, which is the same as that where the protein function occurs.

Ketone Bodies
When carbohydrate is curtailed, as in fasting, starvation, or diabetes, fatty acids are converted to a class of small, four-carbon molecules called *ketone bodies*, usually in the liver. Ketone bodies are more soluble and are transported in the circulation to muscles where they are converted to energy. One of the ketone bodies decomposes spontaneously to produce acetone that is exhaled.

Krebs Cycle
A central, cyclic series of eight biochemical, enzyme-catalyzed reactions taking place in the mitochondria that further degrade carbon resources from carbohydrates, fatty acid oxidation, and protein break down to carbon dioxide, extracting the chemical energy inherent in these structures. This is also known as the *citric acid cycle*.

Ligand
A molecule that binds to a specific protein binding site. Here, fatty acids are ligands to fatty acid binding proteins.

Metabolism
A combination of all catabolic and anabolic reactions.

Metabolic Flux
The rate at which a specific metabolic pathway, or a segment of that pathway, processes metabolites through the system. For example, the flux of glucose through glycolysis

would be the rate at which the combined reactions of glycolysis convert glucose to pyruvate.

Monomeric
A protein with only one subunit; opposite of multimeric, where a number of individual protein molecules form a complex.

Null mice
Laboratory mice in which a gene has been deleted.

Nuclear Hormone Receptors
A large family of proteins in the nucleus that bind various ligands, associate with other transcription factor proteins to form dimers, and then target expression sequences on genes, activating their transcription.

β-Oxidation
A series of enzyme-catalyzed reactions that occur mainly in the mitochondria that converts fatty acids into two carbon units for entrance into the Krebs Cycle.

Phosphorylation
The addition of a phosphate group, usually from ATP, to a simple molecule or to a protein through an ester bond formation. Protein phosphorylation is usually a switch to turn the protein activity on or off.

Peroxisome
A subcellular organelle or compartment.

Polyunsaturated Fatty Acids
Long-chain fatty acids that contain two or more carbon–carbon double bonds.

Protein
A polymer of amino acid linked by a peptide bond. The sequence of the 20 types of amino acids used in protein synthesis is dictated by the gene sequence.

Long-chain fatty acids are paradoxical: they are fuel, structural components, signaling molecules, and, at elevated levels, are toxic. Because of this nature of fatty acids, control of their concentration and movement within cells is important. Central to the biological and biochemical role of fatty acids is a family of proteins referred to as the *fatty acid binding proteins* (FABPs). After early discoveries that the FABPs were the intracellular transport system for fatty acids, their other potential roles, spurred on by the discovery that there were many types of FABPs, have continued to mount. This ancient family of proteins emerged before the divergence of the vertebrate and

invertebrate lines (more than one billion years ago) in response to the necessity of manipulating energy-rich fatty acids. A number of ancillary functions seem to have accrued to this diverse protein family that place them in a central position of energy metabolism, fuel sensing, and monitoring the concentrations of fatty acids derived from the diet.

1 Introduction

1.1 Fatty Acid Binding Proteins

Fatty acid binding proteins (FABPs) are a family of small intracellular proteins with a molecular weight between 14 000 and 15 000 (about 133 amino acids). With intracellular concentrations ranging from 200 to 400 μM, they can represent between 3 and 15% of soluble protein inside cells, depending upon the animal species and the tissue. For example, in humans, heart cells' FABP represents between 3 and 5% of soluble protein, while in the flight muscle cells of migrating Western Sandpipers, it can be 20% of soluble cellular protein. While the protein family has been observed in all animals (vertebrates and invertebrates), there is great three-dimensional structural similarity. The molecule is compact (about 250 × 350 × 400 nm) and, although generally referred to as a *β-clam motif* with one "side" pinched inward, has a barrel shape. Liver- and muscle-type FABP are shown in Fig. 1. All strands are hydrogen-bonded to the preceding and succeeding strands with only one exception, known as the *gap*. This rift in the continuous surface of the barrel (facing the reader in Fig. 1) allows flexibility of the barrel structure without significant disruption of the H-bonded strands around the rest of its circumference. At the "top" of the gap region (the structure is usually oriented with the helix-turn-helix motif at the top and back) is the portal region where the base of the helix-turn-helix and right turns of two β-strands are proximal. It is through the portal region that the ligand probably enters and exits the internal binding site. The internal volume to accommodate ligands has been determined and can vary from about 250 to 440 A^3, with the largest observed for liver FABP that accommodates two, rather than the usual single, fatty acid molecule.

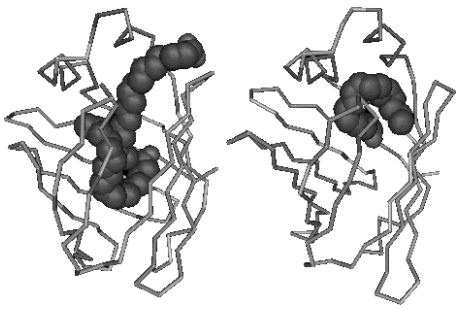

Fig. 1 The peptide backbone structures of rat liver FABP (left panel) with both binding sites filled with oleate and human muscle FABP (right panel) with its single binding site occupied. The images were derived from Cn3D v 4.0 from NCBI with accessions codes 1HMS (muscle protein) and 1LFO (liver protein).

1.2 General Introduction to Fatty Acid Binding Protein Function

FABPs have functions arising from their ability to bind long-chain fatty acids (FAs) and to interact with either the membranous or aqueous fraction of the cell (predominantly the cytoplasm). The potential of interactions between FABPs and other proteins has been supported by evidence that FABPs can alter enzyme kinetics, interact directly with both hormone-sensitive lipase and a cell membrane fatty acid transport protein (CD36), and with peroxisome proliferator–activated receptors (PPAR) in the nucleus that are involved in turning on the expression of various genes. Studies with null mice in which the gene for heart FABP was ablated reflected not only the role of the protein in upregulating genes of FA metabolism but also the compensatory activation of the glycolytic system and apparent reduction of the usual controls of glycolysis.

FABPs can also bind and transport signaling molecules such as bilirubin, prostaglandin E1, and lipoxygenase metabolites of the fatty acid arachidonic acid, although some signaling lipids such as sleep-inducing oleamide in the central nervous system do not bind to brain FABPs. Further, FABPs may protect polyunsaturated fatty acids from free radical damage (peroxidation) through preferential binding of them while greater partitioning of oxidation products of polyunsaturated fatty acids into FABPs, when compared with unilamellar vesicles, may indicate protection of membranes from these monohydroxy fatty acids. Thus, FABPs are involved in intracellular signaling, cell development, and membrane protection, and it appears that they are more than intracellular ferries of poorly soluble hydrophobic molecules.

The idea is developed herein of an interaction between carbohydrate and fatty acid energy metabolism (also known as *fuel sensing* or *fuel preference*) that involves FABPs. Evidence is presented to support the contention that interactions between nonlipid metabolites and FABPs can modulate the partitioning of long-chain FAs into FABP binding sites. Additionally, experimental results showing the potential for reciprocal interaction between FAs and enzymes of glycolysis will be presented. Finally, different FABP types (muscle and liver) respond differently to nonlipid metabolites. The suggested cross talk between the two fuel streams in energy metabolism is centered on substrate cycles involving the enzyme pairs hexokinase-glucose 6-phosphatase and phosphofructokinase-fructose 1,6-phosphatase in muscle and glucokinase-glucose 6-phosphatase in liver. Differential involvement of different FABP types with separate metabolic loci may provide some insight into why there are multiple intracellular fatty acid binding proteins but only a single major extracellular fatty acid binding protein.

1.3 Established Interactions between Carbohydrate and Fatty Acid-based Energy Production

The exchange of rudimentary status information (predominantly concentration) between carbohydrate and FA catabolisms by substrate level control and inhibition/activation of participating enzymes is well established. The reciprocal interaction between FA levels and glucose use, referred to as the *Randle cycle*, suggests that modulation of glycolytic flux depends upon

the mitochondrial production of citrate which, when transported to the cytoplasm, inhibits the major flux generator of this pathway, phosphofructokinase-I (PFK-I). In effect, an elevated citrate concentration inhibits PFK-I and slows the flow of carbohydrate through this point in the pathway. The other major effect of FA is to activate a pyruvate dehydrogenase kinase that phosphorylates mitochondrial pyruvate dehydrogenase and decreases its activity. This curtails the movement of pyruvate into mitochondrial pathways (Krebs Cycle), and an overall decrease is observed in glucose oxidation. This accounts well for the commonly observed decrease of glucose oxidation when lipid levels are increased.

The control of mitochondrial oxidation of fatty acids (β-oxidation) is vested in gating entry of FAs into the mitochondrial matrix through coordinated actions of carnitine palmitoyltransferase I (CPT I), palmitoylcarnitine translocase, and matrical carnitine palmitoyltransferase II. A powerful inhibitor of CPT I and part of the fuel sensing system is malonyl-CoA, the first committed metabolite in FA synthesis and itself a product of cytoplasmic citrate. CPT I is also under phosphorylation control in liver, where phosphorylation by cAMP-protein kinase increases the CPT I activity by 30 to 80%. Thus, an increase in mitochondrially produced citrate (from carbohydrate or other sources) increases its partition to the cytoplasm. An increased cytosolic concentration of citrate inhibits glucose processing at PFK-I and shifts the carbon resources it represents into the pathway that synthesizes fatty acids. The first metabolite along this anabolic pathway is malonyl-CoA that ''shuts down'' entry of fatty acid carbon into the mitochondria where it is oxidized.

1.4 The Involvement of FABP in Metabolism: Working Hypothesis

An additional level of lipidic control of glucose phosphorylation in muscle has recently been reported: CoA esters of long-chain FAs (in rat and human skeletal muscle) and long-chain FAs (in bovine heart) inhibit hexokinase I. This enzyme, by adding a phosphate group to glucose, traps glucose in the cell. There are many older reports that long-chain FAs inhibit a number of other enzymes, but uncertainty arises from those reports since unrealistically large FA concentrations were employed, and detergental effects cannot be ruled out. One careful kinetic study from that pre-FABP era was the inhibitory effect of palmitate on muscle PFK-I with an inhibition constant (K_i) of 25 μM, although the physical binding of FAs to PFK-I has not been studied. Thus, if FAs can influence enzymes of glycolysis (and elsewhere, see below), an involvement of FABP in delivering the FA to the sites of action, presumably through protein:protein interaction, is strongly implicated since such fatty acids have vanishingly small solubility in the aqueous cytosol. Other areas where long-chain FAs have influence, such as the ADP/ATP translocase-porin-hexokinase complex of mitochondria, might also be examined productively.

If FABPs modulate FA metabolism above the level of the genetic machinery, to what signals do they respond? Clearly, any productive modulation of FABP function must act in response to the instantaneous status of the cell/tissue. Some years ago, we suggested that the metabolic status of the cell might be part of the signaling mechanism influencing FA binding

characteristics of various FABPs. Starting with this idea, we began to search for metabolites or conditions within the cell that might influence the FABP operation through modulation of formation of the protein:FA complex. This would probably be an allosteric modulation (in the strictest sense of the term, i.e. not at the fatty acid binding site) since competitive interaction, such as observed with ferri- and ferroheme, would be a binary system (on/off) and not optimally adaptive to a dynamic intracellular milieu. It must be pointed out that, in a strictly thermodynamic sense (i.e. mass action), the effect would result from repartitioning effects. Although it might seem unusual that a small, monomeric protein with a relatively small surface area that changed little upon binding FAs would display allosteric properties usually observed with large, multimeric enzyme systems, such regulation has been demonstrated for other small proteins: cytochrome *c* has a saturable binding site for ATP that regulates the electron transport system and hence oxygen consumption and ATP production. If FABPs are involved in the productive modulation of lipid metabolism and in targeting of FABPs, for example, to the mitochondria, there must be an exchange of information between the binding of FAs and the metabolite status of the cell.

1.5 Criteria for Physiological Relevance of Metabolite Modulation of Fatty Acid Binding to FABP

In the search for possible modulators of FABPs, we compared the degree of binding of reporter ligands (radioactively labeled or fluorescent fatty acids) in the presence and absence of physiological concentrations of metabolites. The assay conditions used in such studies are particularly important since FA binding is effected by ionic strength, pH, and by temperature, and it is vital to mimic the intracellular conditions as closely as possible. Statistically significant changes in binding of reporter ligands to FABP must occur at modulator concentrations encountered under physiological conditions. We examined potential modulators at concentrations found in unstressed tissue since metabolic flux is normally curtailed compared to the maximal flux attainable.

A second level criterion we employ is that the equilibrium dissociation constant (the apparent K_d) of any modulator must also fall within physiological concentration ranges to be part of a normal regulatory network. Finally, interactions that influence FA binding should be consistent with what is known about particular metabolic pathways and physiological states.

1.6 Liver FABP

As an initial test of the working hypothesis, we examined the effect of glycolytic metabolites on the binding of both ^{14}C-labeled oleate and the fluorescent probe *cis*-parinarate (cPnA) to rat L-FABP [27] at 37 °C. To do this, we set the concentration of reporter molecules at the value of the K_d of the ligand, where binding is most sensitive to change. After establishing the FABP:FA complex, we challenged it with test metabolites. We reported that, of the early glycolytic intermediates, the most effective modulators of the ability of L-FABP to bind FAs were glucose and glucose-6-phosphate (G6P). Both of these metabolites increase the ability of FABP to bind long-chain FAs 30 and 40% for 6 mM glucose and 0.25 mM G6P respectively. An alternate binding

assay using the fluorescent probe cPnA provided the same result. In examining the effect of increasing concentrations of these two metabolites on oleate and cPnA binding, the concentrations required to produce a 50% increase in the observed FA binding change were 6 mM and 0.2 mM respectively, within the normal physiological range of glucose and G6P in rat liver. As part of this study, we also examined glucose-1-phosphate (G1P), phosphate ion, fructose-6-phosphate (F6P), fructose-1,6-bisphosphate (F-1,6-P_2), and fructose-2,6-bisphosphate (F-2,6-P_2), phosphoenol pyruvate (PEP), ATP, ADP, AMP and cAMP, NAD^+ and NADH, $NADP^+$ and NADPH, and acetyl-CoA, none of which had an effect on FA binding to rat L-FABP.

A recent study included an examination of the effect of glucose and G6P on [1−^{14}C]oleate binding to human H-FABP and L-FABP. While there was no effect of glucose or G6P on oleate binding as compared to that on the control, the human muscle-type FABP was affected and was similar (although smaller in magnitude) to the effects on bovine H-FABP, as described below.

We extended this study to L-FABP of another rodent species, Richardson's ground squirrel (*Spermophilus richardsonii*), arguing that such a mechanism may be more generally observed. In this system, glucose and G6P also increased the binding of cPnA to the FABP at 37 °C compared to that of the control by $20.6 \pm 0.5\%$ and $41.4 \pm 2.2\%$ respectively ($n = 4$; $p < 0.05$), when examined under the same conditions, as reported before, for rat and using *cis*-parinarate as a fluorescent probe.

In summary, Glc and G6P increased the ability of L-FABP to bind FAs in three mammalian systems and to different degrees. Since the number of ligand molecules bound to the protein was not likely to increase (2 : 1 binding stoichiometry for L-FABP), the effect was probably centered on changes in the binding strength for fatty acid. It should be noted that the effect of glucose on liver-type FABP to glucose is exhibited in frogs (*Rana pipens* and *Rana sylvatica*) and turtle (*Chrysemus picta belli*). The similarity of response in mammals, amphibians, and reptiles suggests a more general phenomenon. We are presently determining amino acid sequences of these proteins and carrying out topological mapping of three-dimensional structures in an attempt to identify surface features of the protein that would best provide information for a phase of site-directed mutational studies that could create the glucose effect or eliminate it.

Because of different experimental protocols and few reports of work with pure proteins, it is difficult to find a general metabolic scenario into which the L-FABP work can be fit. However, recent examination of the effect of oleate on the glycolytic/gluconeogenic balance and glycogen systems of fasted rat hepatocytes is consistent with a role for FABP. In the presence of S4048, an inhibitor of endoplasmic reticulum G6P translocase, oleate increased intracellular G6P 3-fold and glycogen production 1.5-fold. Further, oleate did not have an inhibitory effect on glucokinase (the liver form of hexokinase), but stimulated G6P phosphatase flux (part of the putative hexokinase/G6P phosphatase substrate cycle) and decreased overall lactate production. The increase in G6P was attributed to increased gluconeogenesis. Thus, it appears that long-chain fatty acids, while interacting with early glycolytic enzymes, foster gluconeogenesis in liver. Presumably, an increase in G6P or glucose could increase the partitioning of

FAs to the FABP and behave as a communicative link to lipid status.

Other studies in our laboratory with rat L-FABP have examined the role of the ketone body, D-3-hydroxybutyrate, where, at normal physiological levels (0.14 mM), there was only a small increase in the binding of FA (10%). At levels mirroring diabetic or fasting/starvation hepatic levels (about 7 mM), there was a 45.5% increase in FA binding. The effect was saturable with an inhibition constant, K_i (3-hydroxybutyrate), of 4.9 mM, which is not physiological under euglycemic or nonstarvation conditions. Increased FA binding with elevated 3-hydroxybutyrate (when carbohydrate supply is curtailed as in diabetes or fasting/starvation) could reverse a tendency to gluconeogenesis and modify delivery of available FAs.

1.7 Heart/Muscle FABP

For heart tissue, which has different hexokinase (HK) isoforms and a different FABP type from liver (H-FABP or M-FABP), the situation appears equally complex (note: muscle-type and heart-type FABPs are the same protein and will be referred to as H-FABP here). We showed that bovine heart hexokinase (type I) is inhibited by long-chain fatty acids in a manner that correlates positively with chain length and degree of saturation, but is activated by FAs containing less than 12 carbons. Hexokinase also has a saturable binding site for cPnA and oleate with dissociation constant (K_d) values of 3 μM and 1.3 μM respectively (by fluorescence competition assay), while the short and medium-chain FAs that activated HK did not bind to this site. In other words, long-chain fatty acids bind strongly to hexokinase in a discrete binding site to inhibit the trapping of blood borne glucose within the cell. We can now report work on the FABP purified from bovine heart and for heart-type FABP from the spadefoot toad (*Scaphiopus couchii*).

Figure 2 shows the effects of a number of early glycolytic intermediates on FA binding to the FABP Bovine H-FABP was insensitive to glucose and G6P, as reported for human H-FABP and with toad heart FABP. There was no significant effect on the binding of FAs by physiological concentrations of F6P, but there was significant inhibition of FA binding by $F16P_2$. G1P and P_i did not have any effect on the binding of the fluorescent probe. In contrast to mammalian L-FABP, FA binding by bovine H-FABP was unchanged by 3-hydroxybutyrate.

Unlike hepatic tissue, muscle and heart tissue do not actively produce glucose or ketone bodies. Heart and red skeletal muscles import carbon resources (carbohydrates, fatty acids, and ketone bodies) in response to energy needs and are predominantly aerobic. This essentially unidirectional resource flow is reflected in the poise of muscle metabolic pathways, where the major control points are PFK-I, pyruvate dehydrogenase, and mitochondrial import of FAs. As discussed above, both long-chain FAs and their CoA derivatives inhibit glucose phosphorylation in heart and skeletal muscle. The focus of the interactions in muscle tissue appears to be PFK-I. Long-chain FAs inhibit muscle PFK-I ($K_i = 25$ μM) and F-1,6-P_2 (at 0.03 mM) inhibits FA binding, establishing the possibility of a reciprocal interaction. Elevated FA could decrease glycolytic flux through inhibiting actions on both HK and PFK-I, while decreased F-1,6-P_2 could lift resting state inhibition of FA binding to this FABP type.

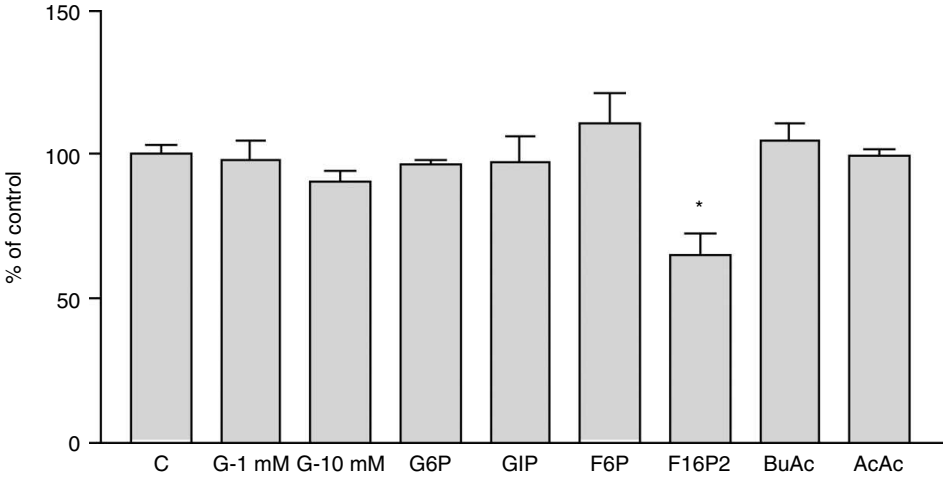

Fig. 2 The effect of various metabolites on the binding of *cis*-parinaric acid (1 μM) to bovine heart FABP compared with the control (no nonlipid metabolite). The assays were carried out at 37 °C, in 50 mM sodium phosphate buffer, pH 7. The assays contained 20 μg of pure proteins per milliliter. The concentrations of metabolites not indicated were G6P, 0.5 mM; F6P, 0.1 mM; F1,6P2, 0.03 mM; 3-hydroxybutyrate (ButAc), 0.1 mM; acetoacetate (AcAc), 0.02 mM. The asterisk indicates statistically significant differences from the control at the 95% confidence limit. The experiments were replicated three to five times with the data representing the means and the error bars the standard deviation.

2 Potential of Formation of Schiff Bases: Nonenzymatic Glycation of FABPs

Carbohydrates that undergo ring opening and formation of a carbonyl group can form Schiff bases with primary amines such as lysine residues that are prevalent in FABP and which appear involved in the collisional mechanism proposed for loading and unloading muscle-type FABPs. Since many of the glycolytic intermediates that can ring open to produce the carbonyl function group influence binding of FAs to FABPs (G6P, glucose, F-1,6-P_2) while G1P and F-2,6-P_2 (which are locked in the closed hemiacetal and hemiketal rings) do not affect FA binding, it is possible that formation of Schiff bases with protein amino groups may cause the observed altered sequestration of FAs. To examine this possibility, we incubated a number of purified FABPs and bovine serum albumin with fluorescently tagged glucose (2-(*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)-2-deoxyglucose; 2-NBDG) at room temperature and in 50 mM sodium phosphate, pH 7.0. We monitored the proteins for indications of covalent fluorescent tagging that would result from Schiff base formation. Periodically, aliquots of the incubation mixtures were removed, and 2-NBDG was separated from protein with a small size-exclusion column. The protein fraction was examined spectrofluorometrically to detect fluorescent tagging (excitation at 473 nm, emission at 532 nm). Figure 3 shows the effect of incubating a number of FABPs and BSA with the fluorescent tag for three days. Only after 48 h of incubation were proteins tagged with the fluorescent

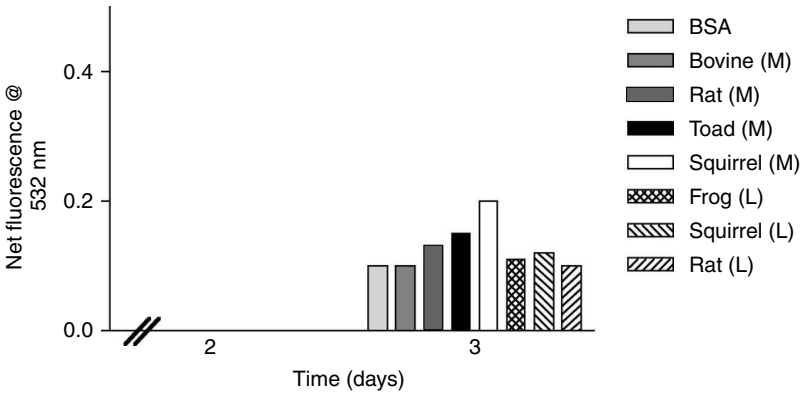

Fig. 3 The time course of glycation of bovine serum albumin and assorted FABPs (30 μg/ml) with D-glucose analog NBDG (80 μM) in 10 mM sodium phosphate buffer, pH 7.0, and 1% (w/v) sodium azide at 25 °C. Over the time course, as proteins (after separation from small molecules with size exclusion) became glycated, they became fluorescently tagged (473-nm excitation, 532-nm emission). A fluorescence value of 0.5 represents 1-nmol fluorescent tag.

carbohydrate derivative at detectable levels. The slowness of the nonenzymatic glycations we observed was consistent with nonenzymic glycation rates of human serum albumin (days) using other fluorometric methods. Thus, it is unlikely that Schiff base formation was significant during the time required for making the measurements of the effects of metabolites on FA binding (minutes).

3 Theoretical Effects and Implications of Reciprocal Cross Talk

3.1 How Much Fatty Acid Would Be Available to Interact with Hexokinase?

The similarity of dissociation constants of HK and FABP for oleate and cPnA leads to an important question surrounding such mutual interactions. Given the large cellular concentration of FABP, is there enough unbound FA to interact with HK? To model the amount of unbound FA in the presence of two different binding proteins requires the concentration value of both proteins, the total FA concentration, and the equilibrium dissociation constants (K_d) of both binding proteins to be known. The intracellular concentration of FABP has been reported to be 85 μM, while some estimates provide ranges of 200 to 400 μM. An intermediary value of 250 μM muscle-type FABP was used in the following model.

Determining the molar concentration of HK in heart tissue is more difficult since it is not directly reported in the literature. We can estimate from the maximal tissue activity (V_{max}) and the measured catalytic rate constant (k_{cat}) of the enzyme a reasonable enzyme concentration since $V_{max} = k_{cat}[E]_T$, where $[E]_T$ is the total enzyme. The k_{cat} of type I HK is 64 s^{-1}, while the maximal activity in mammalian heart has been reported between 5 and 10 μmol min^{-1} g^{-1} tissue for mammals. A value of 8 μmol min^{-1} g^{-1} tissue (porcine heart) was used here.

Finally, the estimate must convert the tissue weight–based activities to concentrations: the assumption of 75% water content will suffice. Thus, with $V_{max} = 8\ \mu mol\ min^{-1}\ g^{-1}$ and $k_{cat} = 64\ s^{-1}$, we can estimate a minimum $[E]_T = 3\ \mu M$. Using a K_d of 1 μM for FABP and 1.3 μM for HK, we can model equilibrium concentrations of unbound FA and degree of saturation of both protein systems at different initial FA concentrations. Figure 4(a and b) shows the result of this very simple equilibrium model.

The amount of free FA in the simple model in which FABP is present is enough to saturate HK, as indicated by Fig. 4(a) that shows the binding isotherms of FABP at various free FA concentrations, and

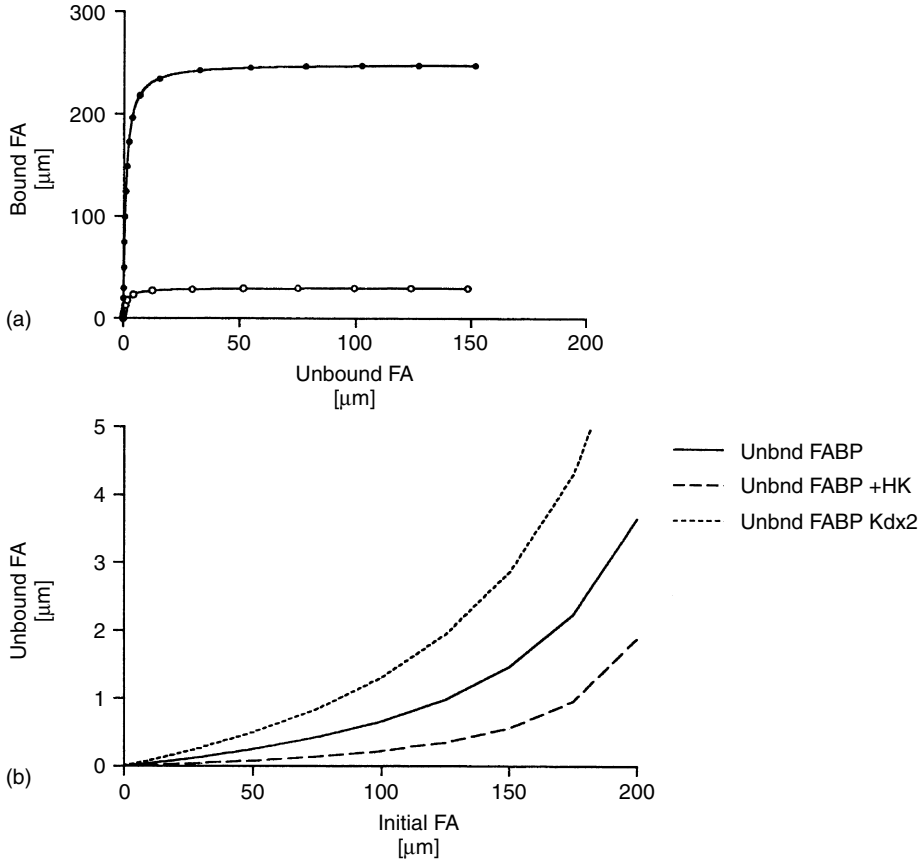

Fig. 4 (a) The degree of saturation of a muscle-type FABP and hexokinase versus the amount of unbound fatty acid (oleate) in the model system. The saturation curve of hexokinase (lower curve) was generated using the concentration remaining after FABP equilibrated its binding site with ligand. The hexokinase binding curve was magnified by 10 to be observable at this scale. (b) The residual concentration of unbound fatty acid at various initial fatty acid concentrations in the presence of FABP and of FABP plus hexokinase. The upper line indicates the effect on the amount of unbound fatty acids if binding strength of FABP was decreased by a factor of two (i.e. K_d increased twofold).

the binding curve of HK using the FA remaining unbound in the presence of FABP. Figure 4(b) shows the estimated concentration of unbound FA in the presence of FABP, of FABP plus HK, and the effect on the amount of unbound FA when the K_d value of the FABP for oleate is doubled (i.e. binding is weakened), as is seen in toad muscle FABP in the presence of F-1,6-P_2. Thus, even with FABP present, providing very low concentrations of unbound FAs, unbound FA could be sequestered on HK.

4
Difference in Modulation of Fatty Acids and between Different Types of FABP

The data suggest that liver FABPs and muscle types of FABP respond different nonlipid metabolites. While the liver types increase the degree of FA binding in the presence of glucose and G6P, with an activation of binding also elicited by ketone bodies, muscle type does not respond to glucose or G6P, is inhibited by F-1,6-P_2, and does not respond to ketone body. If FABPs are involved in fuel selection, the different metabolic poise of these two tissues would demand that they operate differently. The differential response may offer some part of an explanation of the presence of different FABPs in different tissues and perhaps multiple forms in some tissues.

5
Where Else Should We Look?

5.1
Other Enzymes Influenced by Fatty Acids

The influence of long-chain FAs on enzyme kinetics, specifically hexokinase, and PFK-I have been noted above. FAs also have an effect on the myoglobin system and bind strongly to cytochrome *c* altering their functions in the cell. As part of an examination of potential sites of interference during hyperlipidemia, we examined a battery of enzymes to see if elevated FA concentrations altered their reaction kinetics. We examined the enzymes of glycolysis (HK, PFK, PK, lactate dehydrogenase, aldolase, triosephosphate isomerase, pentose phosphate cycle (G6P dehydrogenase), the citric acid cycle (citrate synthase, malate dehydrogenase, and α-ketoglutarate dehydrogenase), and β-oxidation (CPT-I)). Additionally, we examined the effects of fatty acids on the enzymes that degrade reactive oxygen species (catalase, superoxide dismutase). Table 1 shows the results of incubation of enzymes of major metabolic systems with oleate. In these studies, all enzymes were obtained from commercial sources, and assays were established that provided maximal specific activities. We compared the maximal enzyme activities over a range of FA concentrations with the highest being 0.2 mM. The enzymes listed above, and not in Table 1, showed no effect upon incubation with long-chain fatty acids.

The clearest conclusion from this survey is that most enzymes are not sensitive to concentrations of FAs. Those enzymes that are sensitive to FAs are those that have controlling functions on various metabolic pathways and indicate that there is a closer connection between lipid and carbohydrate metabolism than has generally been appreciated.

5.2
The PPAR System

The peroxisomal proliferator-activated receptors (PPAR) are lipid-binding proteins,

Tab. 1 The effect of oleate on the specific activity of selected enzymes and proteins. The values are mean specific activity ± standard deviation and the number of trials are given in parentheses.

Enzyme	***No oleate***	***0.2 mM oleate***
	[μmol min^{-1} mg^{-1} protein]	***[μmol min^{-1} mg^{-1} protein]***
Glycolysis		
Hexokinase (bovine heart)	2.74 ± 0.10 (3)	0.55 ± 0.03 (3)[b]
Phosphofructokinase (rabbit muscle)	18.6 ± 0.9 (3)	0.32 ± 0.07 (3)[b]
Pyruvate kinase (rabbit muscle)	9.8 ± 1.6 (6)	10.2 ± 1.6 (3)
Lactate dehydrogenase (rabbit muscle)	1.8 ± 0.1 (5)	1.7 ± 0.01 (5)
Krebs cycle		
Citrate synthase (porcine heart)	54.8 ± 2.5 (3)	51.3 ± 3.1 (3)
Pentose phosphate cycle		
G-6-P dehydrogenase (yeast)	26.6 ± 0.7 (3)	0.20 ± 0.04 (3)[b]
G-6-P dehydrogenase (bovine adrenals)	0.67 ± 0.04 (6)	0.55 ± 0.20 (6)
Electron transport		
Ferrocytochrome *c* oxidation[a]	0.050 ± 0.005 (4)	0.100 ± 0.015 (4)[b]
Reactive oxygen		
Catalase (bovine liver)	11.2 ± 0.4 (6)	11.4 ± 0.3 (5)
Superoxide dismutase (SOD) (bovine erythrocyte)		
L-DOPA oxidation-no SOD	0.250 ± 0.002 (3)	0.260 ± 0.005 (3)
L-DOPA oxidation-10 mg SOD	0.13 ± 0.1 (3)	0.14 ± 0.01 (3)

[a] Cytochrome *c* autoxidation was measured with Hansatech DW2/2 oxygen electrode at pH 7, 37 °C, in 50 mM sodium phosphate buffer with an initial [cytochrome *c*] = 0.25 mM. Units are μmol O_2 min^{-1} mg^{-1} protein.
[b] Indicates values that were significantly different ($p < 0.05$).

members of the nuclear hormone receptors family, and transcription factors that initiate expression of genes after forming a complex with the retinoid X receptor proteins (RXR). The PPAR:RXR complex binds to specific expression elements of the gene. PPARs (types α and γ interact with FA-loaded FABPs in the nucleus, and a fatty acid is transferred to the PPAR. It is the PPAR:FA complex than can then bind to the RXR. Fatty acid binding proteins along with bound fatty acids are translocated into the nucleus where they interact with the PPARs. FABPs without bound FAs are excluded from the nuclear matrix. Conceivably, alteration of the binding strength of FABPs for their fatty acids would influence the amount of import of the loaded FABP and perhaps the ease at which the FA is transferred to a PPAR. If, in their interaction with nonlipid metabolites, FABPs mediate a potential interaction between glycolytic status and the expression of FA metabolic enzymes and proteins, they are more than transport barges for poorly soluble fatty acids.

6 Summary

The binding of FA to FABP can be modulated by nonlipid metabolites.

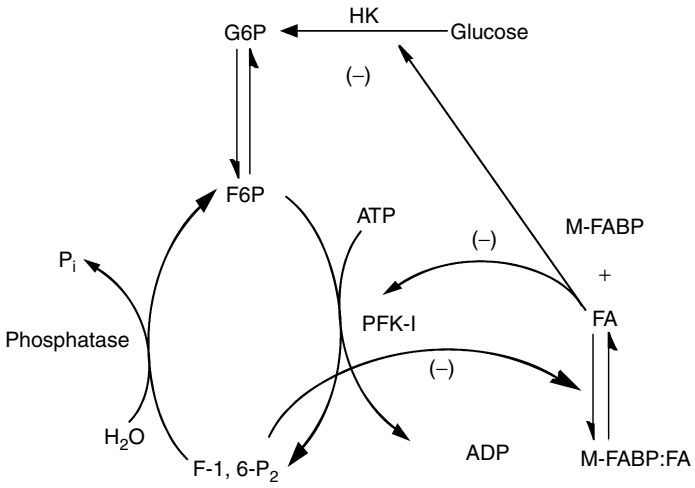

Fig. 5 A model of the interaction scheme between early glycolysis and FABP in mammalian muscle or heart. The bracketed negative signs indicate inhibition of either enzyme activity or binding to FABP. The values of the inhibition constants are given.

Figure 5 summarizes one model (muscle FABP/PFK-I) that forms the basis of present endeavors. There is a differential response of L- and M-FABP to metabolites. These differential responses may offer insight into why there are different FABP types expressed in the same tissue. While the ability of FAs to bind to cytoplasmic enzymes may alter the concentrations of unbound FAs (usually sequestered in membranes), the reverse, where FABPs can influence enzyme substrates, must be evaluated. A consequence of FABP interactions with glycolytic intermediates may influence the concentration of available glucose in the case of hexokinase and F-1,6-P_2 in the case of PFK-I. Significant fractions of cytoplasmic glycolytic substrates could be associated with FABPs. As in conservation of critical, thermodynamic characteristics of fatty acids binding to FABPs across species, the effects of metabolites on FA binding to FABPs being retained across diverse species support this possible new role for FABPs.

Acknowledgments

Many thanks to John A. Blakely, my longtime research associate, for discussions, reading of the manuscript, and technical expertise, and to my colleagues Janet M. Storey and Kenneth B. Storey, Carleton University, for stimulating discussions over the years. The work of a number of students has been essential in this work, notably (in no particular order), Steven Wiseman, Jaime F. Snow (nee Claude), Stephen J. Crozier, Daniel Jardine, Dr. Monica Henry, Philip Karpowicz, Dr Kevin Larade, Shauna Flavelle, Megan Miller, Ashley Woods (glycation work), Luke E. Gauthier, Nathalie Boudreau, Dr Justin MacDonald, Ted Wright, Vanessa Dewling, Christopher Martin, Jonathan D. Schinkel, R. James Allan, and Dr Frank O'Dea. The National Sciences and Engineering Research Council of Canada, the Heart and Stroke Foundation of New Brunswick and Mount Allison University must be acknowledged

for the funding that allowed the research to proceed.

Keywords

Cancer Gene
A mutated gene that has been causally implicated in oncogenesis (i.e. conferring a clonal growth advantage) by at least two independent reports confirming somatic/germline mutations in primary patient specimens.

Chromosomal Translocation
Genomic rearrangements that create chimeric genes; the most common mutation in cancer genes, often resulting in fusion proteins that include an oncogenic kinase catalytic domain and regulatory elements of an unrelated protein.

Human Kinome
A catalog of the 518 protein kinase genes encoded by the human genome and viewable at www.kinase.com.

Kinase Domain
A conserved sequence of amino acids composed of 12 subdomains and responsible for the catalytic transfer of the γ-phosphate of ATP to protein substrates.

Neoplasm
Any new growth of tissue that is both uncontrolled and progressive.

Abbreviations

ALCL	anaplastic large-cell lymphoma
ALK	anaplastic lymphoma kinase
ALL	acute lymphoblastic leukemia
ARG	Abl-related gene
ATM	ataxia telangiectasia mutated kinase
CDK	cyclin-dependent kinase

CML	chronic myelogenous leukemia
EGFR	epidermal growth factor receptor
ERK	extracellular signal regulated kinase
FGFR	fibroblast growth factor receptor
FLT3	FMS-like tyrosine kinase 3
GDNF	glial cell line–derived neurotrophic factor
GOF	gain-of-function
GRB	growth factor receptor bound
JAK	Janus kinase
JNK	Jun-amino-terminal kinase
JNKK	JNK kinase
LCK	T-lymphocyte protein–tyrosine kinase
MAP	mitogen-activated protein
MEK	MAP kinase–kinase
NSCLC	non–small-cell lung cancer
NTRK	neurotrophin tyrosine receptor kinase
PDGFR	platelet-derived growth factor receptor
PDK1	3-phosphoinositide-dependent protein kinase-1
PI3K	phosphoinositide 3-kinase
PIM	proviral integration of the moloney murine leukemia virus
PLCγ	phospholipase C γ
PTEN	phosphatase and tensin homolog
PTK	protein–tyrosine kinase
RET	rearranged in transformation
RTK	receptor protein–tyrosine kinase
SCF	stem cell growth factor
SGK	serum glucocorticoid regulated kinase
SH	Src homology domain
STAT	signal transducers and activators of transcription
STRAD	STE20-related adapter
STK11	serine–threonine kinase 11
TCR	T-cell receptor
TPR	translocated promoter region

Cancer genes that encode protein kinases are the most commonly mutated class of genes to be causally linked to the progressive outgrowth of malignant neoplasms. Protein kinases operate as important molecular switches that impinge, directly or indirectly, upon an integrated signaling circuitry that often becomes genetically reprogrammed, through successive mutations, to transmit many of the growth-stimulating and survival signals that govern the transformation of normal human cells into a cancerous cell mass. Of the 291 genes recently included in a comprehensive catalog of known human cancer genes, 9.3% (27 distinct genes) encode kinase domain sequences. This number far exceeds a random prediction of 6.3

genes (2%) and reinforces the hypothesis that a vast majority of human cancer cells carry genetic defects in the growth-signaling circuitry that enable these cells to grow autonomously and evade cellular senescence and death. First, we provide a general overview of a prototypical growth-signaling circuit and a detailed analysis of the canonical Ras/Raf/MEK/ERK pathway, because it has a central role in cancer cell signaling. This analysis is followed by a discussion of each of the kinases known to be mutated in cancer; we will describe the domain organization and normal function(s) of the protein, its oncogenic alterations in cancer and how this alters its activity, and identify the tumor/cancer types in which these changes are most common.

1 Overview of the Prototypical Growth-signaling Circuit

1.1 Signaling Pathways in Normal Human Cells

Protein phosphorylation is the most common posttranslational protein modification in mammalian cells and is a fundamental mechanism for the direct or indirect control of physiological processes of crucial importance to cell growth and survival. Protein phosphorylation is mediated by a superfamily of protein kinases comprising ~2% of the human genome, and a diverse collection of unrelated substrate proteins, comprising more than 10% of the genome. Collectively, these proteins control the responsiveness of a cell to its environment by coordinating complex functions such as normal embryonic development, cell division, differentiation, adhesion, motility, and metabolic activity.

All eukaryotic protein kinases have conserved a ~250 to 300 amino acid ''kinase domain,'' composed of 12 subdomains and 12 relatively (>95%) invariant residues. The kinase domain uses the γ-phosphate of ATP or GTP to generate phosphate monoesters using two types of acceptors: (a) protein phenolic groups of tyrosine amino acids (i.e. the protein-tyrosine kinases, PTK) and (b) protein alcohol groups on serine/threonine amino acids (i.e. the protein Ser/Thr kinases). A third class, called dual specificity protein kinases, are able to phosphorylate either substrate (both Tyr and Ser/Thr). The kinase domain folds into a two-lobed three-dimensional structure separated by a deep hydrophobic cleft. When in a catalytically active conformation, the kinase domain is able to perform three interdependent functions: (a) binding and orienting the ATP/GTP phosphate donor as a complex with a divalent cation (Mg^{2+} or $Mn2^{2+}$), (b) binding and orienting the protein substrate, and (c) transferring the γ-phosphate from ATP/GTP to the acceptor hydroxyl residue of the protein substrate. The latter reaction occurs within a subdomain referred to as the *catalytic loop*. In a normal cell, the catalytic activity of most protein kinases is constrained by an intrasteric inhibition at both the ATP/GTP and substrate peptide binding sites within the kinase domain. This suppression of catalytic activity is often achieved when a ''pseudosubstrate'' sequence, located outside of the kinase domain and containing the consensus recognition sequence of a true

peptide substrate lacking the phosphoryl acceptor, interacts with the kinase domain and thereby blocks or distorts the active site. This form of autoinhibition is common among both the PTK and Ser/Thr kinase families and serves as just one example of the multiple layers of regulatory constraint normally exerted on a protein kinase in order to maintain a balance between the rate of cell-cycle progression and cell death. Other important examples of mechanisms capable of relieving the autoinhibition of a protein kinase include the role of protein–protein interactions (both homo- and hetero-dimerization), and activating ligands and/or second messengers. Limiting the intensity/duration of changes in protein phosphorylation are protein phosphatases and a diverse array of mechanisms controlling the biogenesis and half-life of the protein kinase.

Our understanding of how multiple protein kinases normally function within a signaling pathway has been derived largely from studies focused on delineating immediate upstream and downstream interactions through gain- and loss-of-function manipulations, arranging these interactions into orderly and conditional cascades of molecular events, and ultimately linking cell surface receptors to an effector that is capable of eliciting a biological response. Analyses of such linear pathways have provided valuable insights into the interactions between components, both within and between certain pathways.

Many of the genes that cause cancer encode receptor PTKs (RTK), a subclass of transmembrane-spanning receptor that responds to certain extracellular cues (ligands) with a disinhibition of their intrinsic PTK activity. The cytoplasmic Ser/Thr protein kinases Akt and Raf function intracellularly as important points for the convergence of many of the signals emanating from these upstream oncogenic RTKs. A

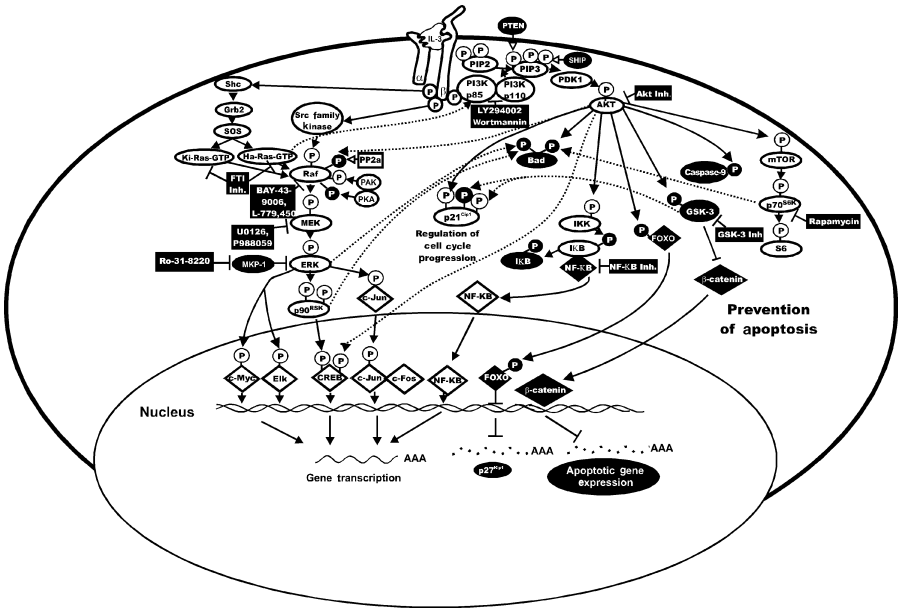

Fig. 1 Interactions between Raf/MEK/ERK and PI3K/Akt pathways and sites of action of small molecular weight signal transduction pathway inhibitors.

typical graphic representation of such a signaling network is shown in Figure 1, encompassing Akt, Raf, and several interactive signaling pathways regulating the phosphorylation of its downstream effectors, such as c-Myc, Elk, CREB, NF-kappa B, and Forkhead. These phosphorylated proteins, in turn, mediate the effects of Akt and Raf on gene transcription, and on the proliferation, growth, differentiation, and survival of the cell.

1.2 Genetic Rewiring of Signaling Circuits in Cancer Cells

Most PTKs that have thus far been implicated in cancer undergo mutations that result in a loss of their normal autoinhibition of catalytic activity. In certain signaling ''cascades,'' such as the mitogen-activated protein (MAP) kinase pathway (Fig. 1), this loss of repression would be sufficient to trigger the constitutive activation of all downstream components, since the activity of MAP kinases is dependent on activation of the upstream kinase. However, the regulation of kinase activity is generally more complex, making it more difficult to predict how the oncogenic deregulation of a given kinase may contribute to cellular transformation. For example, the activation of 3-phosphoinositide-dependent protein kinase-1 (PDK1) is not sufficient to induce the phosphorylation of certain of its downstream substrates (e.g. p70 ribosomal S6 kinase). Rather, these substrate proteins must first undergo conformational rearrangements that render their PDK1 phosphorylation sites accessible to PDK1. Such modes of substrate-directed regulation are not frequently integrated into a typical signaling diagram. A traditional view of signaling networks provides a valuable and empirical foundation for generating meaningful hypotheses pertaining to the potential downstream effects that a constitutively active (mutant) oncogenic kinase might have within a network such as that shown in Figure 1. However, these predictions are often intuitive and can be somewhat simplistic when applied to the downstream effectors of a protein kinase such as PDK1.

Systems biology and computational modeling have now entered the field of cell biology and are changing the way scientists think about signaling networks in complex biological systems. A goal of systems biology is to understand, from a global perspective, the constellation of biological behaviors that can emerge from single/multiple mutations within the components of a cell's extensive network of signaling modules. This approach to interrogating cells, together with high-throughput genomic and proteomic screening approaches, promises to lead to the identification of unexpected ''cluster groups'' of genes/proteins of similar or related functions that are mutually influenced by experimentally defined mutational events. Though this approach presents a formidable challenge, it constitutes a major new frontier in the study of signaling in cancer, and has gained a significant degree of traction with the recent identification of a limited and well-characterized set of cancer genes encoding signaling molecules.

1.3 Identification of Activating Mutations in Cancer Genes Encoding Signaling Molecules

Of the 291 genes recently included in a comprehensive catalog of known human cancer genes, 27 distinct genes encode

kinase domain sequences (see Cancer Genome Project: http://www.sanger.ac.uk/CGP/). With the identification of each of these mutated kinases, it will now be possible to apply the principles of systems biology to a global analysis of how the introduction of each mutant kinase alters cellular behavior, and to exploit genomic and proteomic strategies to extract responsive cluster groups. With such an expansive inventory of new data, computational modeling can then begin to evaluate whether a specific combination of mutations (''hits'') would be capable of transforming a normal cell into a cancer cell. The oncogenic themes likely to arise from such an effort can be expected to vary among cancers and according to the sequence in which genetic mutations are introduced within a given cell.

The success of the epidermal growth factor receptor (EGFR) kinase inhibitor gefitinib (Iressa®) in the treatment of non–small-cell lung cancer (NSCLC) and the ABL kinase inhibitor imatinib (Gleevec®) in treating chronic myeloid leukemia (CML) demonstrate the potential for targeting specific activating mutations in protein kinases that promote proliferative signals in cancer cells. However, it is also now apparent that the effectiveness of such treatments will be limited, and will be critically dependent on identifying the dominant genetic lesion responsible for activating a given kinase in each malignancy, and thereafter developing drugs to target this Achilles' heel. For example, only about 10 to 19% of patients with NSCLC respond to treatment with Iressa®, although a majority of these patients express the EGFR. However, a subset of patients, representing ~10% of lung cancers with tumors positive for mutations clustered around the ATP-binding pocket of the tyrosine kinase domain, respond dramatically to Iressa®. Therefore, the patient's response to therapy will be dependent on correctly matching a given kinase inhibitor to the causal oncogenic event in each case. As a prelude to this emerging effort, this article will describe each of the 27 protein kinases known to be capable of functioning as dominant human cancer genes in turn. We will describe the domain organization and normal function(s) of the protein, its oncogenic alterations in cancer and how this alters its activity, and identify the tumor/cancer types in which these changes are most common. First, however, we begin with an analysis of the canonical Ras/Raf/MEK/ERK pathway that is of such importance in cancer cell signaling.

2 Ras/Raf/Mek/Erk Pathway

The Ras/Raf/MEK/ERK pathway is a central signal transduction pathway, which transmits signals from multiple cell surface receptors to transcription factors in the nucleus. This pathway is frequently referred to as the MAP kinase pathway because it can be stimulated by mitogens, cytokines, and growth factors. The pathway can be activated by Ras stimulating the membrane translocation of Raf. This pathway also interacts with many different signal transduction pathways including phosphatidylinositol 3-kinase (PI3K)/Akt and Jak/STAT (See below).

2.1 Ras

Ras is a small GTP-binding protein, which is the common upstream molecule of several signaling pathways including Raf/MEK/ERK, PI3K/Akt, and RalEGF/Ral. The switch regions of the Ras proteins are in part responsible for the switch

between the inactive and active states of the protein. Switching between these states has been associated with conformational changes in the switch regions, which allows the binding of GTPase activating proteins and guanine nucleotide exchange factors. When Ras is active, GTP is bound, whereas when Ras is inactive GDP is bound. GTPases inactivate the Ras proteins while guanine nucleotide exchange factors activate the Ras proteins by stimulating the removal of phosphate from GTP or addition of GTP, respectively.

Different mutation frequencies have been observed between *Ras* genes in human cancer. There are three different Ras family members, Ha-Ras, Ki-Ras and N-Ras. The Ras proteins show varying abilities to activate the Raf/MEK/ERK and PI3K/Akt cascades; Ki-Ras has been associated with Raf/MEK/ERK while Ha-Ras is associated with PI3K/Akt activation. Amplification of *Ras* proto-oncogenes and activating mutations that lead to the expression of constitutively active Ras proteins are observed in approximately 30% of all human cancers. The effects of Ras on proliferation and tumorigenesis have been documented in immortal cell lines. However, antiproliferative responses of oncogenic Ras have also been observed in non-transformed fibroblasts, primary rat Schwann cells, and primary fibroblast cells of human and murine origins. This premature G_1 arrest and subsequent senescence is dependent on the Raf/MEK/ERK pathway, and has been shown to be mediated by many cell-cycle inhibitory molecules including $p15^{Ink4b}$/$p16^{Ink4a}$ and $p21^{Cip1}$.

2.2 Raf

The Raf protein family consists of A-Raf, B-Raf, and Raf-1, which are involved in the regulation of proliferation, differentiation, and apoptosis, induced after cytokine stimulation. The Raf proteins have three distinct functional domains: CR1, CR2, and CR3. The CR1 domain is necessary for Ras binding and subsequent activation. The CR2 domain is a regulatory domain. CR3 is the kinase domain. Deletion of the CR1 and CR2 domains produces a constitutively active Raf protein due, in part, to the removal of phosphorylation sites, which serve to negatively regulate the kinase in the CR2 domain.

The *A-Raf* gene is located on the X chromosome in humans and produces a 68-kDa protein. The highest level of A-Raf expression in the adult is in the urogenital tract. A-Raf deletion results in postnatal lethality, attributed to neurological and gastrointestinal defects. The role of A-Raf has remained elusive. A-Raf is the weakest Raf kinase in terms of activation of ERK activity. ERK activation occurs in A-Raf knock-out mice indicating that other Raf isoforms can compensate for this deficiency. Some studies have indicated that A-Raf has an important role in stimulating the growth of hematopoietic cells. Moreover, we have observed that overexpression of activated A-Raf will abrogate the cytokine-dependence of hematopoietic cells.

The *B-Raf* gene is located on chromosome 7q34. B-Raf encodes a 94-kDa protein. The highest expression of B-Raf is in the testes and neuronal tissue. The *B-Raf* gene produces splice variants, the physiological roles of which have not yet been elucidated. The loss of B-Raf expression in mice results in intrauterine death between days 10.5 and 12.5. The B-Raf knock-out mouse embryo displays enlarged blood vessels and increased apoptosis of differentiated endothelial cells. This is an indication that Raf kinases can regulate

apoptosis. B-Raf and Raf-1 activity are negatively regulated by Akt phosphorylation. Akt also has other effects on the presentation of apoptosis, and will be discussed in more detail later. In contrast, other studies have shown that overexpression of B-Raf in Rat-1 cells results in decreased apoptosis because of inhibition of caspase activity. Historically, B-Raf is the strongest Raf in terms of induction of MEK activity, as determined by *in vitro* kinase assays. B-Raf activation is different from either Raf-1 or A-Raf activation; it requires the phosphorylation of only one regulatory residue, whereas activation of Raf-1 and A-Raf require two phosphorylation events. B-Raf is also regulated by Akt and the serum glucocorticoid regulated kinase (SGK). Recently it has been shown that B-Raf may be required in the activation of Raf-1, and that B-Raf and Raf-1 may be induced at different times following stimulation. Moreover, the three different Raf proteins may have different subcellular pools, and Raf-1 and A-Raf may be localized, in some cases, to the mitochondrion. The roles of B-Raf in human neoplasia will be discussed later.

The *Raf-1* gene is located on chromosome 3p25 and produces a 74-kDa protein. The *Raf-1* proto-oncogene was the first *Raf* gene to be cloned. It is the cellular homolog of *v-Raf* contained in the naturally occurring acute retrovirus 3611-MSV. *Raf-1* is ubiquitously expressed in adult tissues with highest expression in muscle, cerebellum, and fetal brain. It is the most studied Raf isoform. A dominant-negative version of Raf-1 inhibits Ha-Ras-induced transformation and tumor formation. Raf-1 has important roles in apoptosis as it phosphorylates and inactivates Bad. Raf-1 phosphorylates and co-immunoprecipitates with Bcl-2 and also regulates Bag and Bad expression, in BCR/ABL expressing cells. Recently, Raf-1 has been proposed to have roles independent of MEK/ERK that are often involved in regulating cell-cycle progression and apoptosis. These new roles for Raf-1 will be discussed below.

The activation of the three Raf isoforms is complex and not totally understood. Ras is known to activate B-Raf independently of Src activity while Raf-1 and A-Raf require an Src-like kinase for complete activation. An Src-like kinase phosphorylates Tyr340 and Tyr341 on Raf-1 and Tyr301 and Tyr302 on A-Raf, which are not present in B-Raf. B-Raf contains aspartic acid at the corresponding residues. Aspartic acid residues are negatively charged and are believed to confer a constitutively active configuration at this site. B-Raf is constitutively phosphorylated on Ser445 (a site equivalent to Ser338 in Raf-1), which is phosphorylated as a result of Ras activation. The Ras binding domains of B-Raf and Raf-1 have a greater affinity for Ras than A-Raf. This suggests that A-Raf may have a primary activator other than Ras. Phosphorylation of the activation loop of Raf-1 and B-Raf is necessary, but not sufficient, for activation. The deletion or mutation of inhibitory phosphorylation sites present at certain residues by site-directed mutagenesis activates Raf proteins. Akt also phosphorylates Raf-1 at Ser259, which has been associated with inhibition of Raf-1 activity.

Several protein kinases are known to regulate Raf-1 activity. cAMP-dependent protein kinase inhibits Raf-1. cAMP activates PKA, resulting in phosphorylation of Raf-1 on Ser43 and Ser621, and inhibiting Raf-1 activity. This contrasts with B-Raf activation in response to cAMP-dependent protein kinase. Raf-1 is activated through $p21^{Cip1}$-associated protein. Activation of conventional protein kinase C isoforms (α, β, and γ) stimulates Raf-1 activity in

a baculovirus system. Protein kinase Cε is associated with c-N-Ras and Raf-1 and is necessary for activation of Raf-1 by phorbol 12myristate 13acetate in fibroblasts. RKIP, a Raf-1-interacting protein, inhibits Raf-1 activation of MEK1. 14-3-3 proteins are known to bind Raf. The interaction of 14-3-3 proteins with phosphorylated Ser259 and Ser621 inhibits Raf-1. Protein phosphatase 2A can remove the phosphate on Ser259, allowing Raf to become disassociated from 14-3-3. This allows Raf-1 to assume a conformation in which it can be phosophorylated and activated by other kinases including $p21^{Cip1}$-associated protein and Src family kinases.

Raf-1 was originally characterized as phosphorylating MEK1, but B-Raf is the primary MEK1 activator in bovine brain extracts, NIH 3T3 cells, PC12 cells and other cells. Raf-dependent activation of p90 ribosomal S6 kinase ($p90^{Rsk}$) and NF-κB are activated by an Raf-1 mutant, which no longer binds or phosphorylates MEK1. This suggests that Raf-1 has physiological substrates other than MEK1. Recently, the possible roles of Raf-1 in the Raf/MEK/ERK signal transduction pathway have become a matter of controversy due to the discovery that B-Raf is the more potent activator of MEK and that many of the ''functions'' of Raf-1 still persist in Raf-1 knock-out mice, but not in B-Raf knock-out mice. Raf-1 has been postulated to have important roles in cell-cycle progression, activation of the p53 and NF-κB transcription factors, and the prevention of apoptosis. Raf-1 has been postulated to have nonenzymatic functions and serve as a docking protein. Raf-1 has been proposed to have important functions at the mitochondrial membrane. Interestingly, it has been shown that Bcr-Abl (see Sect. 3.1.2) may interact with Raf-1 to alter the distribution of Bag at the mitochondrial membrane and hence regulate (prevent) apoptosis in hematopoietic cells.

Recently, the mechanism of B-Raf regulation has been more intensively investigated. B-Raf activation may occur through the GTP-binding protein Rap-1, which is in turn activated by RA-guanine nucleotide exchange factor-1 and Src. cAMP-dependent protein kinase may activate Src in some cells, resulting in Rap-1 activation. There are three regulatory residues on B-Raf – Ser444, Thr598, and Ser601. The Ser/Thr kinases that phosphorylate these residues are not known. Activated B-Raf can interact with Ras, which in turn results in the activation of Raf-1. B-Raf can activate MEK, which results in the activation of ERK and downstream kinases and transcription factors. Rheb and 14-3-3 proteins can bind and inhibit B-Raf activity. B-Raf can also be negatively affected by phosphorylation by either SGK or Akt. Akt has been shown to phosphorylate B-Raf on three residues – Ser364, Ser428, and Thr439 (see below). However, Akt may have greater affinity for other substrates besides B-Raf. SGK has been proposed to be a more relevant kinase for regulating B-Raf through phosphorylation of Ser364. B-Raf may also activate Raf-1 *via* Ras-GTP. While Rap-1 activates B-Raf, it may also serve to inactivate Raf-1. Thus the pathways for activation and inactivation of B-Raf and Raf-1 are complex, and may at times appear contradictory.

2.3 Mek

MEK proteins are the primary downstream targets of Raf. The *MEK* family of genes consists of five genes: *MEK1, MEK2, MEK3, MEK4, and MEK5*. This family of dual specificity kinases has both Ser/Thr and Tyr kinase activity. The structure

of MEK consists of an amino-terminal negative regulatory domain and a carboxy-terminal MAP kinase-binding domain that is necessary for binding and activation of ERKs. Deletion of the regulatory MEK1 domain results in constitutive MEK1 and ERK activation.

MEK1 is a 393 amino acid protein with a molecular weight of 44 kDa. MEK1 is modestly expressed in embryonic development and is elevated in adult tissue, with the highest levels detected in brain tissue. Knock out of functional MEK1 results in lethality due to placental vascularization problems. Mice with dominant-negative MEK1 have also been generated; these mice were viable although defects in T-cell development occurred. MEK1 requires phosphorylation of Ser218 and Ser222 for activation. The substitution of these residues with aspartate or glutamic acid led to an increase in activity and foci formation in NIH3T3 cells. Mutated MEK1 constructs demonstrate that the activation of ERK does not require a functional MEK1 kinase domain. Replacement of the amino-terminus of MEK1 with the hormone-binding domain of the estrogen receptor produces a construct with kinase activity responsive to the presence of estrogen analogs. This construct is an invaluable tool in research into MEK1 signaling. Studies with this construct demonstrated that activated MEK1 could abrogate the cytokine dependency of certain hematopoietic cells. Constitutive activity of MEK1 in primary cell culture promotes senescence and induces p53 and $p16^{INK4a}$, whereas the opposite was observed in immortalized cells or cells lacking either p53 or $p16^{INK4a}$. Constitutive activity of MEK1 inhibits NF-κB transcription, by negatively regulating $p38^{MAPK}$ activity. Pharmaceutical companies have developed inhibitors of MEK. The two most widely used are U0126 and PD98059, because they are commercially available. These two inhibitors have IC_{50}s of 70 nM and 2 μM, respectively. PD98059 inhibits activation, while U0126 inhibits activity. Thus, these two inhibitors have a noncompetitive mechanism of inhibiting ERK activity.

2.4 Erk

The main physiological substrates of MEK are the members of the ERK (extracellular signal regulated kinase), or MAP kinase, family of genes. The ERK family consists of four distinct groups of kinases: ERK, Jun amino-terminal kinases (JNK1/2/3), $p38^{MAPK}$ (p38 $\alpha/\beta/\gamma/\delta$), and ERK5. In addition, there are ERK3, ERK4, ERK6, ERK7, and ERK8 kinases, which are related to ERK1 and ERK2, but have different modes of activation, with biochemical roles that are not as well characterized. The ERK 1 and 2 proteins are the most studied with regards to Raf signaling in hematopoietic cells.

ERK1 and *ERK2* encode 42 and 44 kDa proteins, respectively. These proteins were originally isolated by their ability to phosphorylate microtubule-associated protein 2. ERKs are activated through dual phosphorylation of threonine and tyrosine residues by MEK1 kinases. This dual phosphorylation activates ERK; however, ERK activity is downregulated by serine/threonine phosphatases, tyrosine phosphatases, or dual specificity phosphatases. ERK dimerization occurs subsequent to phosphorylation. This dimerization maintains the activation of ERK and promotes nuclear localization of the protein. Activated ERK preferentially phosphorylates serine/threonine residues preceding a proline.

Mice lacking ERK1 have defective T-cell development, similar to transgenic mice containing a dominant-negative MEK1. Recently, different roles have been suggested for ERK1 and ERK2. While these two proteins are often detected at similar levels, their expression patterns may change. ERK1 has been postulated to inhibit ERK2 expression. Increased ERK2 activity is associated with cell proliferation. Interestingly, ERK1 has been associated with cognitive brain functions including learning.

2.5 Roles of the Ras/Raf/Mek/Erk Pathway in Neoplasia

Mutations at three different Ras codons (12, 13, and 61) convert Ras into a constitutively active protein. These point mutations can be induced by environmental mutagens. Given the high level of mutations that have been detected at Ras, this pathway has always been considered a key target for therapeutic intervention. Approximately 30% of human cancers have Ras mutations. Ras mutations are frequently observed in certain hematopoietic malignancies including myelodysplastic syndromes, juvenile myelomonocytic leukemia, and acute myeloid leukemia. Ras mutations are often one step in tumor progression and mutations at other genes (chromosomal translocations, gene amplification, and tumor suppressor gene inactivation) have to occur for a complete malignant phenotype to be manifested. Pharmaceutical companies have developed many farnesyl transferase inhibitors, which suppress the farnesylation of Ras, preventing it from localizing to the cell membrane.

As stated previously, there are three different *Ras* genes – *Ki-Ras*, *Ha-Ras*, and *N-Ras*. The biochemical differences between these Ras proteins have remained elusive. *Ki-Ras* mutations have been more frequently detected in human neoplasia than *Ha-Ras* mutations. Ras has been shown to activate both the Raf/MEK/ERK and the PI3K/Akt pathways. Thus, mutations at Ras should theoretically activate both pathways simultaneously. Ras mutations have a key role in malignant transformation as both of these pathways can prevent apoptosis as well as regulate cell-cycle progression. Recently it was shown that there is specificity in terms of the ability of Ki-Ras and Ha-Ras to induce the Raf/MEK/ERK and PI3K/Akt pathways. Ki-Ras preferentially activates the Raf/MEK/ERK pathway, while Ha-Ras preferentially activates the PI3K/Akt pathway. Therefore, if Ras inhibitors could be developed which would specifically inhibit one particular Ras protein, it might be possible to inhibit one of the downstream pathways. This might, under certain circumstances, be advantageous. Furthermore, decreases in ERK expression may affect differentiation responses. Thus in certain tumors, one might desire to inhibit the effects that Ras has on the PI3K/Akt pathway as opposed to the effects it has on Raf. Targeting of Ha-Ras as opposed to Ki-Ras might inhibit apoptosis suppression by Ha-Ras, but not the effects Ki-Ras has on cell-cycle progression and differentiation.

Overexpression of the Raf/MEK/ERK cascade has been frequently observed in human neoplasia. A prime consequence of this activation may be the increased expression of growth factors, which can potentially further activate this cascade by an autocrine loop. Many cytokine and growth factor genes contain transcription factor binding sites, which are bound by transcription factors (Ets, Elk, Jun, Fos, CREB) that are often activated by the

Raf/MEK/ERK cascade. Identification of the mechanisms responsible for activation of this cascade has remained elusive. Genetic mutations at Raf, MEK, or ERK were thought to be relatively rare in human neoplasia. For many years, numerous scientists were of the opinion that the activation of the Raf/MEK/ERK cascade was mainly due to mutations at Ras, and hence studies aimed at elucidating the mechanisms of Ras activation were launched.

While mutations at the *Raf* gene in human neoplasia have been detected, they have not until recently gained the clinical importance that Ras mutations readily achieved. Because of more innovative, high-throughput DNA sequencing, scientists have recently discovered that the *B-Raf* gene is frequently mutated in certain cancers including hematopoietic tumors. Approximately 60% of the melanomas surveyed in one study were observed to have mutations at *B-Raf* (see Sect. 3.2.1). This result provides relevance to the investigation of signal transduction pathways because, by understanding how *B-Raf* is activated, one Ras-dependent and one Ras-independent event, scientists could predict why a single missense mutation in *B-Raf* permitted ligand-independent activation, whereas in similar mutation events it could not be predicted whether the mutation events would result in either Raf-1 or A-Raf activation, as they requires multiple activation events. Interestingly, in 22 tumors (melanomas, colorectal, and NSCLC tumors) that were examined, there were 10 with mutations at *B-Raf* and 10 with mutations at Ras. Out of these two tumors had mutations at *B-Raf* and Ras; two did not have mutations at either gene. Thus *B-Raf* transformation does not appear to require Ras, and many tumors had mutations at one or the other, but not both, genes. Recently, it has been suggested that B-Raf mutations occur during the process of progression of the tumor, and not during the establishment of the tumor. This was suggested by analysis of *B-Raf* mutations in different developmental stages of melanomas.

Raf inhibitors have been developed and some are being used in clinical trials. Raf-1 has at least 13 regulatory phosphorylation residues. This makes inhibition of Raf activity difficult, as certain phosphorylation events stimulate Raf activity while others inhibit and promote Raf association with 14-3-3 proteins, rendering it inactive though present in the cytoplasm. Certain Raf inhibitors were developed which inhibit the Raf kinase activity as determined by assays with purified Raf proteins and substrates (e.g. MEK). Some Raf inhibitors may affect a single Raf isoform (e.g. Raf-1), others may affect Raf proteins, which are more similar (Raf-1 and A-Raf), while other Raf inhibitors may affect all three Raf proteins (Raf-1, A-Raf and B-Raf). We have observed that the L-779,450 inhibitor suppresses the effects of A-Raf and Raf-1 more than those of *B-Raf*. Knowledge of the particular *Raf* gene that is mutated or overexpressed in certain tumors may provide critical information for planning treatment for the patient. Inhibition of certain *Raf* genes might prove to be beneficial, while inhibition of other *Raf* genes under certain circumstances might prove detrimental. Thus, the development of unique Raf inhibitors may prove useful in human cancer therapy.

Activation of Raf is complex and requires numerous phosphorylation and dephosphorylation events. Prevention of Raf activation by targeting kinases (e.g. Src or Akt) and phosphatases involved in Raf activation may be a mechanism to inhibit/regulate Raf activity. It is worth noting that some of these

kinases normally inhibit Raf activation (e.g. Akt). A major limitation of this approach would be the specificities of these kinases and phosphatases. Inhibiting these kinases/phosphatases could result in activation or inactivation of other proteins and would have other effects on cell physiology.

Dimerization of Raf proteins is critical for their activity. We often think of a single Raf protein carrying out its biochemical activity. However, Raf proteins dimerize with themselves and other Raf isoforms to become active. Drugs such as coumermycin, which inhibit Raf dimerization, and others such as geldanmycin, which prevent interaction of Raf with 14-3-3 proteins, suppress Raf activity. Various Raf isoforms may dimerize and result in chimeric molecules, which may have different biochemical activities. Little is known about the heterodimerization of Raf proteins.

Downstream of Raf lies MEK. Currently, it is believed that MEK1 is not frequently mutated in human cancer. However, aberrant expression of MEK1 has been detected in many different types of cancer, and mutated forms of MEK1 will transform fibroblast, hematopoietic, and other cell types. Useful inhibitors to MEK have been developed, which display high degrees of specificity. The successful development of MEK inhibitors may be due to the relatively few phosphorylation sites on MEK involved in activation/inactivation. MEK inhibitors are in clinical trials.

Downstream of MEK lies ERK. To our knowledge no small-molecular-weight ERK inhibitors have been developed yet. However, inhibitors to ERK could prove very useful as ERK can phosphorylate many targets (Rsk, c-Myc, Elk, etc.), which have growth-promoting effects. There are at least 2 ERK molecules regulated by the Raf/MEK/ERK cascade, ERK1 and ERK2. Little is known about the different *in vivo* targets of ERK1 and ERK2. However, ERK2 has been postulated to have pro-proliferative effects while ERK1 has antiproliferative effects. Development of specific inhibitors to ERK1 and ERK2 might eventually prove useful in the treatment of certain diseases.

The MAP kinase phosphatase-1 (*DUSP1*) removes the phosphates from ERK. MAP kinase phosphatase-1 is mutated in certain tumors and could be considered to be a tumor suppressor gene. An inhibitor to this phosphatase has been developed (Ro-31-8220).

3 Protein Kinases Encoded by Cancer Genes

3.1 Protein-tyrosine Kinase Family

3.1.1 Receptor Protein-tyrosine Kinase Subfamily

More than half (55%) of the protein kinases included in the current census of human cancer genes are RTKs. Somatic chromosomal translocations that result in the fusion of a given tyrosine kinase domain of one gene with the regulatory region of another unrelated gene are most common. In many instances, a number of different genes will form chimeric transcripts with the same *RTK* gene. Generally, the fusion proteins encoded by these translocated cancer genes phosphorylate their protein substrates in a ligand-independent manner. Such mutations are often found in lymphomas, leukemia, epithelial neoplasms, and solid tumors.

ALK The anaplastic lymphoma kinase (*ALK*) gene, located on human chromosome 2p23, is expressed only in the

small intestine, testis, and brain, and encodes a Type Ia membrane protein (carboxy-terminal kinase domain oriented intracellularly) with a glycosylated amino-terminal extracellular region that binds the ligands pleiotrophin and midkine. Ligand-binding specificity is dependent on two cysteine-rich clusters that are adjacent to the major ligand-binding domain. The extracellular domain of ALK also contains a low-density lipoprotein-A module, suggesting that ALK may also interact with low-density lipoproteins. Other motifs present in the extracellular domain include a glycine-rich patch and MAM domain (Meprin/A-5/protein-tyrosine phosphatase Mu), which may play a role in mediating certain cell–cell interactions. Like other RTKs, discussed below, tyrosine residues in the intracellular domain of ALK regulate its intrinsic kinase activity, and provide phosphorylation-dependent recruitment sites for the Src homology 2 (SH-2) domains of various adapter proteins and enzymes that propagate intracellular signaling cascades. For ALK, these include the insulin receptor substrate-1, Shc protein, and phospholipase C-γ. The adapter protein Shc forms complexes with GRB2 (growth factor receptor-bound protein 2) and the Son of Sevenless protein to activate the Ras/Raf/MEK/ERK signaling cascade (Fig. 1). Although ALK-deficient mice do not display any marked developmental defects, the *drosophila* homolog (i.e. *DAlk*) is required for normal development of the gut musculature. A common feature among all ALK chimeric proteins is the presence of an oligomerization domain in the partner protein and oligomerization-mediated kinase activation. Although the intracellular localization of these fusion proteins are predominantly determined by the amino-terminal fusion partner, all fusion proteins result in aberrant activation of multiple downstream signaling cascades that are responsible for cellular transformation. Approximately half the non-Hodgkin's lymphomas classified as anaplastic large-cell lymphomas (ALCL) are associated with a common somatic chromosomal translocation, t(2;5)(p23;q35). This chimeric gene encodes an oncogenic fusion protein comprised of the complete cytosolic and kinase domains of ALK joined to the amino-terminal 117 amino acid residues of the nucleolar phosphoprotein nucleophosmin. The transforming activity of the fusion protein (nucleophosmin-ALK) requires the activation of its kinase function, a result of the oligomerization mediated by the nucleophosmin segment. Although less common, other ALK fusion partners include TPM3, TFGxl, TFGs, ATIC, CLTC, MSN, TPM4, MyH9, RANBP2, ALO17, and CARS. Constitutive ALK signaling activates pathways that either enhance proliferation or target the PI3K/Akt survival pathway. Proliferation is enhanced by activation of the MAP kinase pathway through Ras or phospholipase C-γ (PLC-γ). PLC-γ-mediated hydrolysis of membrane phospholipids produces localized increases in inositol triphosphate and diacyglycerol, which, in turn, stimulate the release of Ca^{2+} from intracellular stores and the activity of the Ser/Thr protein kinase C. Although the precise nature of the interaction between PI3K and ALK is unknown, a potential complex includes nucleophosmin-ALK and the regulatory p85 subunit of PI3K with GAB2, Shc, and/or CrkL, an interaction recently identified in the human Karpass 299 cell line.

EGFRs The EGFR subfamily of RTKs encompasses four closely related receptors, EGFR (also known as ErbB-1 or HER1),

ErbB-2 (HER2), ErbB-3 (HER3), and ErbB-4 (HER4), which drive proliferation, differentiation, survival, and cell motility. Of these, *EGFR* and *ErbB-2*, located on chromosomes 7p12 and 17q21, respectively, are best characterized for their role in human cancers. EGFRs are comprised of an extracellular domain (containing two receptor ligand-binding domains and a furin-like domain), a transmembrane region, and the cytoplasmic domain (containing the catalytic kinase domain). EGFR signaling is normally triggered by the binding of its natural ligand, such as EGF, betacellulin, heparin-binding EGF, and transforming growth factor-α. These EGFR ligands are all membrane-bound proteins containing one or more EGF-like motifs that interact with the receptor. Members of the EGFR subfamily are capable of forming as many as 10 different homodimers and heterodimers when occupied by an appropriate ligand and the affinity of each EGFR combination differs for each ligand. For example, an EGFR homodimer binds EGF, betacellulin, and heparin-binding EGF with about the same affinity, whereas an ErbB2:3 heterodimer preferentially binds the heregulin β isoform versus the heregulin α isoform. Receptor dimerization initiates the transphosphorylation of the PTK activation loop, which is required for optimal kinase function. Multiple tyrosine residues in the cytoplasmic tail are also phosphorylated, permitting the recruitment of adapter signaling proteins. Adapter proteins containing SH-2 domains recognize and bind phosphorylated Tyr residues and feed into signaling pathways including the Ras/Raf/MEK/ERK, PI3K/Akt, and PLCγ/PKC pathways. The result is the activation of proliferative and cell-survival signals. Potential biological responses are complex and diverse, depending upon receptor composition, ligand identity, and duration of signaling. The *EGFR (ErbB-1)* and *ErbB-2* genes are commonly amplified, rearranged, or mutated in many human cancers, including head and neck cancer, NSCLC, breast cancer, and gliomas. For example, EGFR is overexpressed in 40to 80% of NSCLCs. As discussed above (see Sect. 1.3), however, only a subset of these patients responds to the EGFR kinase inhibitor Iressa®. Therefore, overexpression by itself is not sufficient to predict responses, and the evidence suggests that activating mutations are also required. In NSCLC, these activating mutations are somatic and clustered around the ATP-binding pocket of the EGFR catalytic domain. All mutations are heterozygous and consist either of small, in-frame deletions, or amino acid substitutions within exons 17 to 19. Importantly, these mutations lead to increased responsiveness to EGF and also confer susceptibility to the inhibitor Iressa®. In contrast, rearrangements within the extracellular domain of EGFR are common in gliomas and colorectal cancer, and are associated with kinase activation. A number of monoclonal antibodies targeting the extracellular ligand-binding region (e.g. cetuximab) have been developed to specifically block such mutant EGFRs. The *erbB-2* gene is amplified in 20 to 30% of breast and ovarian cancers. ErbB-2 does not directly bind to ligands and yet its overexpression promotes oncogenesis through decreases in attenuation pathways and signal potentiation. ErbB-2 amplifies signaling indirectly by increasing the ligand affinity of its heterodimeric binding partners (i.e. EGFR, ErbB-3, and ErbB-4) and prolonging the surface expression of these RTKs by slowing their rate of internalization. In addition, ErbB-2 enhances EGFR recycling and reduces lysosomal targeting.

FGFRs The fibroblast growth factor receptor (FGFR) family is comprised of four high-affinity RTKs (FGFR1-4) that share several structural features in common, including two or three immunoglobulin-like domains and an acidic box in their amino-terminal extracellular domains, a single transmembrane domain, and an intracellular PTK domain split by a short (14 amino acid) insertion. While three of these RTKs have now been classified as cancer genes (*fgfr1–3*), the fourth (*fgfr4*) is also known to be overexpressed in mammary and ovarian carcinomas. The chromosomal locations of the *fgfr1-fgfr3* genes are 8p11.2, 10q26, and 4p16.3, respectively. Distinct FGFR mutations have been shown to mediate a variety of autosomal disorders of bone growth and embryonic development and a discussion of each would be beyond the scope of the present article. However, it is important to note that the majority of mutant FGFRs identified to date possess elevated PTK activity relative to their wild-type counterparts, resulting in ligand-independent activation. While mutations in the extracellular domain of FGFRs have been associated with dwarfism, Pfeiffer syndrome, and other developmental abnormalities, the most common mutations associated with human cancer involve a subset of acquired (somatic) translocations that target chromosome band 8p11 (*fgfr1*), and will serve as an instructive example of how the constitutive activation of FGFRs might contribute to oncogenesis. Crystal structures of an inactive FGFR1 reveal that the activation loop normally occludes substrate tyrosine binding to the catalytic site. In solution, equilibrium exists between this inactive conformation (called *cis* inhibition) and the active loop conformation. The family of fibroblastic growth factors (FGFs) capable of activating the FGFRs includes at least 24 members sharing 30 to 50% amino acid sequence homology, and are designated FGF-1 through FGF-24. Certain FGF family members are considered to be oncogenic (e.g. FGF-3, FGF-4, FGF-5, and FGF-6) and all have been implicated in the control of a variety of biological processes. In response to ligand occupancy, FGFRs undergo a ligand-induced conformational shift that promotes dimerization and *trans*phosphorylation of tyrosine residues in the activation loops of the binding partner. This leads to a movement of the activation loop away from the catalytic site that permits substrate access, while *trans*phosphorylation provides binding sites for recruitment of signal transducers and activators of transcription (STATs) *via* their SH-2 domains. In acute myelogenous leukemia, chromosomal rearrangements lead to a fusion between the ZNF198 mRNA at exon 17 and FGFR1 at exon 9, containing the kinase domain. *ZNF198* is a widely expressed gene that encodes a 155-kDa protein with five Zn finger–related motifs (known as MYM domains) that are retained in the ZNF198-FGFR1 chimeric protein. ZNF198-FGFR1 has constitutive PTK activity and is thought to rely on STAT5 activation in the transformation of hemopoietic cells. FGFR1 phosphorylation of STAT5 promotes dimerization, and dimeric STATs are exported to the nucleus, where these latent transcription factors associate with the promoters of early response genes such as *c-fos, c-jun*, and *c-myc* and initiate transcription of cell-cycle regulatory genes. FGFRs are mitogenic for endothelial cells and play a significant role in angiogenesis by stimulating the production and release of agents that break down basement membranes.

FLT3 FMS-like tyrosine kinase 3 (FLT3) is a member of the platelet-derived growth

factor receptor (PDGFR) family and is located on human chromosome 13q12. Four of the five members of the PDGFR gene family are regarded as authentic cancer genes. These include KIT and the PDGRs type A (PDGFRA) and PDGFR type B, in addition to FLT3. FLT3 contains five extracellular ligand-binding immunoglobulin-like (Ig) domains and a cytoplasmic split tyrosine kinase motif. FLT3 is expressed in hematopoietic cells, placenta, gonads, and brain. The ligand for FLT3 is a hematopoietic growth factor termed FL (Flt3 ligand). The *fl* gene encodes a transmembrane protein, but alternative splicing can result in the generation of a soluble form of the FLT3 ligand. Flt3 binds both the membrane-bound and soluble forms of FL. FL binding activates tyrosine kinase activity and stimulates proliferation. Although FL does not efficiently induce proliferation of normal cells by itself, it does reinforce signaling *via* other growth factor receptors. FLT3 deficient mice develop normally, although they possess specific deficiencies in primitive B-lymphoid progenitors, and $FLT^{-/-}$ stem cells are impaired in their ability to reconstitute T cells and myeloid cells when transplanted into bone marrow. Thus, FLT3 signaling is critical for normal development of stem cells and B cells. FLT3 signaling is mediated by phosphorylation-dependent interactions between its carboxy-terminal cytoplasmic tail and enzymes and adapter proteins, such as the regulatory p85 subunit of PI3K, RAS/GTPase activating protein, PLC-γ, Shc, and GRB2. The activity of FLT3 is normally autoinhibited by intramolecular interactions between the cytosolic juxtamembrane domain and kinase domain, preventing ATP and substrate from binding to the activation loop. Although FLT3 is not normally expressed in mature hematopoietic cells, somatic mutants of the *flt3* gene are frequently expressed in hematological malignancies. Examples include FLT3 expression in 70% of acute myelogenous leukemias, about 30% of acute lymphoblastic leukemias (ALL), and some CML cases in lymphoid blast crisis. Although a number of different activating mutations of the *flt3* gene have been documented, two types are by far the most common. Small tandem duplications of amino acids within the juxtamembrane domain and point mutations within the activation loop occur in 24 and 7% of acute myelogenous leukemia patients, respectively. Although duplications within the juxtamembrane domain are highly variable, each is thought to move this cytosolic domain away from the activation loop, triggering kinase activity. Point mutations of the nucleotides encoding Asp835, within the FLT3 activation loop, similarly disrupt the autoinhibition of kinase activity. Since FLT3 mutations tend to be associated with a poor prognosis in leukemia, it is thought that mutant FLT3 may cooperate with other leukemia oncogenes to confer a more aggressive phenotype of this disease.

KIT The proto-oncogene *c-kit*, located on human chromosome 4q12, encodes the stem cell growth factor (SCF) receptor KIT/SCFR, a human homolog of the *v-kit* Hardy-Zuckerman 4 feline sarcoma viral oncogene. The domain organization of KIT has been conserved by all members of the PDGFR family of glycosylated, single-pass transmembrane proteins containing five extracellular immunoglobulin-like domains and a split intracellular PTK domain. The cytosolic juxtamembrane region appears to provide a crucial level of KIT autoinhibition, as mutations within this region are often associated with constitutive, ligand-independent, kinase activity.

The importance of this receptor in normal hematopoiesis and melanogenesis was established by the finding that naturally occurring germline loss-of-function mutations result in developmental defects in both processes. In a normal cell, KIT activation stimulates the proliferation and differentiation of cells such as hematopoietic stem cells, mast cells, and germ cells through the canonical RTK pathway; that is, SCF binding initiates KIT dimerization and the transphosphorylation of the dimeric KIT subunits. These phosphotyrosine residues enable the docking of SH-2 domain–containing signaling molecules including GRB2, SHP-1 (a protein-tyrosine phosphatase expressed in hematopoietic cells), and members of the Src family of cytosolic tyrosine kinases. The dephosphorylation of KIT by SHP-1 functionally limits the activity of this RTK and the half-life of the receptor is limited by the adapter protein APS, which promotes ubiquitin-mediated degradation of KIT through the recruitment of E3 ubiquitin ligase c-Cbl. Thus, both SHP-1 and APS may function as tumor suppressors for KIT-induced malignancies. Downstream of KIT, PI3K-dependent activation of Akt and the phosphorylation/inactivation of the proapoptotic protein Bad appear to be crucial mediators of KIT-induced cellular transformation. More than 30 gain-of-function (GOF) mutations in *KIT* result in a constitutively active kinase and have now been identified in a variety of different human malignancies. These mutations can generally be found in one of two regions. Deletions of a few codons within the autoinhibitory juxtamembrane region, encoded by exon 11, are observed in gastrointestinal stromal tumors and single amino acid changes in exon 17, in the carboxy-terminal half of the kinase domain, are associated with mast cell leukemia and to a lesser extent with T-cell lymphoma and acute myelogenous leukemia. Other GOF point mutations have been identified in exon 13, encoding the amino-terminal half of the KIT kinase domain. In addition to these somatic mutations, GOF mutations of the *KIT* gene have also been associated with germline tumors such as testicular seminomas and ovarian dysgerminomas. Experimentally, the co-expression of KIT and its ligand SCF has been shown to enhance the autocrine growth of cells and tumorigenesis. Approximately 80% of the patients with activating *KIT* mutations in exon 11 respond to the EGFR inhibitor Gleevec®.

MET The human *Met* (HGF receptor) gene is located on chromosome 7q21-q31 and is expressed in a variety of organs and cell types. Following its glycosylation, the MET precursor protein (190 kDa) is cleaved into a 50 kDa α-chain and 140-kDa β-chain that are linked *via* disulfide bonds. After membrane insertion of the β-subunit, these heterodimers form a mature receptor consisting of an extracellular α-subunit joined to a single-pass membrane protein (i.e. β-subunit) with a large ectodomain and intracellular PTK domain. Stimulation of MET by its natural ligand, hepatocyte growth factor/scatter factor, can lead to a broad range of responses in normal cells, such as increased proliferation, scattering, enhanced motility, and angiogenesis. The downstream effects of MET activation include the stimulation of both the PI3K and MAP kinase pathways (see Fig. 1). A series of autophosphorylation events, including phosphorylation within the β-chain activation loop at Tyr1234 and Tyr1235, and a substrate docking site at Tyr1249 and Tyr1356, stimulate MET catalytic activity and facilitate the docking of SH-2 domain- and

MET-binding domain (MBD)-containing proteins including Src, GRB2, PI3K, and PLC-γ. Proteosomal degradation of MET is mediated through interactions between the multisubstrate docking site of MET and c-Cbl. A score of MET-activating mutations, several of which are located in the PTK domain of the β-subunit, have been identified in various solid tumors and metastatic carcinomas. Of particular interest are various germline as well as somatic missense mutations within exons 16 to 19 of the *Met* gene. These mutations commonly generate amino acid substitutions within the kinase domain. For example, the N1118Y substitution impacts the highly conserved ATP-binding site while Y1253D affects the regulatory site on MET in squamous cell cancer. MET overexpression has been observed in various tumor specimens, including NSCLC, mesothelioma, pancreatic cancer, osteosarcoma, ovarian carcinoma, as well as metastatic lesions. Studies of small cell lung carcinoma have revealed that interactions between PI3K and MET sustain survival and motility. Direct involvement of MET in the process of oncogenesis is implicated by the presence of germline as well as somatic missense mutations, which characterize hereditary papillary renal carcinoma.

NTRK1 and NTRK3 Neurotrophins are a family of four secreted and growth-promoting polypeptides known to be widely distributed in both neural and non-neural tissues – that is, nerve growth factor, brain-derived neurotrophic factor, and neurotrophins 3 and 4 (NT3 and NT4). Three homologous neurotrophin tyrosine receptor kinases (NTRK1–3) are responsive to one or more of the neurotrophins and both NTRK1 and NTRK3 are known to form oncogenic fusion proteins in soft tissue tumors. The human *Nrtk1* and *Nrtk3* genes are located on chromosomes 1q21-q22 and 15q25, respectively. While nerve growth factor is the preferred ligand of NTRK1, NTRK3 binds neurotrophin 3 with high affinity. NTRK receptors share a common structural organization of their amino-terminal extracellular domains, which includes three leucine-rich 24-residue motifs flanked by two cysteine clusters and a pair of juxtamembrane C2-type immunoglobulin-like domains. The major ligand-binding domains are localized to the membrane-proximal immunoglobulin-like domains, which are also required to inhibit spontaneous dimerization and activation of the receptors in the absence of ligand. The intracellular carboxy-terminus of these receptors contains a tyrosine kinase domain plus several Tyr-containing motifs. These motifs are involved in regulating kinase activity and also in the phosphorylation-dependent recruitment of several small G proteins (e.g. Ras, Rap-1, and members of the Cdc-42/Rac/Rho family) and intermediates in the MAP kinase, PI3K, and PLCγ signaling cascades, ultimately resulting in activation of gene expression in a cell-dependent manner. Chromosomal translocations that form oncogenic fusion proteins containing the kinase domains of either NTRK1 or NTRK3, have been identified in various carcinomas. In the case of NTRK1, oncogenic activity may be conferred by a chromosomal translocation involving the 5′-dimerization domain of a non-muscle tropomyosin gene and the 3′-kinase domain of *Ntrk1*, giving rise to a constitutively active PTK. In other cases, rearrangements have been identified involving either the 5′-*TPR* (translocated promoter region) from the *Met* oncogene, or the 5′-region of *TFG* (*trk* fused gene). The *TPR-Ntrk1* translocation

forms a fusion protein composed of the amino-terminal portion of TPR and the carboxy-terminal tyrosine kinase domain of NTRK1. Transgenic mice that express human TPR-NTRK1 in the thyroid develop follicular hyperplasia and papillary carcinoma. Chromosomal translocations involving *Ntrk3* often involve the breakpoint regions t(12;15)(p13;q25) and result in a chimera consisting of the NTRK3 kinase domain and the dimerization domain of the ETV6/Tel transcription factor. The oncogenic fusion proteins produced by any of the rearrangements discussed above exhibit three common characteristics that are absent from NTRK1 or NTRK3; ubiquitous cytosolic expression, ligand-independent dimerization *via* coiled-coil domain interactions, and constitutive kinase activity. These fusions have been implicated in the genesis of human colon carcinoma and papillary thyroid carcinoma in the case of NTRK1, and in secretory breast carcinoma and congenital fibrosarcoma in the case of NTRK3.

PDGFRA and PDGFRB PDGFRA and PDGFRB are encoded by genes located in human chromosomes 4q11-q13 and 5q31-q32, respectively. PDGFRA exhibits a pronounced structural and sequence similarity with members of the PDGFR family, including PDGFRB. The main distinction between PDGFRA and PDGFRB is exemplified by their ligand preferences, with PDGFRB selectively interacting with PDGF homodimers containing B type polypeptide chains (PDGF BB) while PDGFRA interacts more promiscuously with the PDGF AA, BB, and AB dimers. In addition, these receptors exhibit temporally distinct and tissue-specific activities in the mammalian embryo and adult. For example, PDGFRA expression in the nervous system coincides with the development of glial cells, which includes processes of glial cell migration and proliferation. The functional PDGFRA consists of an extracellular domain containing five immunoglobulin-like domains punctuated by eight N-linked glycosylation sites, a transmembrane domain, and two cytoplasmic kinase domains (domains 1 and 2). The extracellular immunoglobulin-like domains are essential for the proper folding of the PDGFRA protein, thereby enabling receptor–ligand interactions. Ligand engagement induces receptor dimerization and autophosphorylation, which generates phosphorylation-dependent recruitment sites for adapter proteins and enzymes capable of activating the PI3K and MAP kinase pathways (e.g. Src, PI3K, PLC-γ, the Crk group of adapter proteins, and SHP-2). PDGFRA is also capable of stimulating c-Jun N-terminal kinase (JNK1) to promote apoptosis, and inhibit cell-cycle progression *via* the cyclin-dependent kinase (CDK) inhibitor $p21^{Cip1}$. Signaling through the PDGFRA also stimulates membrane ruffling, cytoskeletal rearrangements, and migration in a cell-type-specific manner. PDGFRA activity is limited by ligand-induced Src activation and receptor trafficking/internalization. In cancer, a potentially activating deletion of an 81 amino acid stretch within the fifth immunoglobulin-like domain of the extracellular stalk of PDGFRA has been described. This deletion mutant is found amplified in glioblastoma, where it is likely to give rise to an alternatively folded receptor capable of sustaining PDGFRA catalytic activity in the absence of ligand. Recently, a transforming *PDGFRA* deletion mutant lacking immunoglobulin-like domain-encoding exons 8 and 9 has also been identified in gliomas. This mutant protein is capable of autophosphorylation and, therefore, activation in the absence

of PDGF. In addition, mutations and deletions within the PDKFRA activation loop (exon 18) and juxtamembrane region (exon 12), that have been detected in gastrointestinal pacemaker cell tumors (i.e. "gastrointestinal stromal tumors"), are also capable of producing ligand-independent activation. PDGFRA and its ligands have also been reported to facilitate tumorigenesis in the absence of genetic mutations, by establishing autocrine signaling loops, as in the case of medulloblastomas where autocrine stimulation promotes metastasis.

RET The glial cell line–derived neurotrophic factor (GDNF) family, consisting of GDNF, neurturin, artemin, and persephin, all transmit signals promoting neuronal survival, proliferation, and differentiation *via* the transmembrane receptor tyrosine kinase RET (rearranged in transformation) and its co-receptors GFRα-1 to -4. RET is normally expressed throughout the nervous system, within neural crest derived cells, and the urogenital system, and is required for neuronal and kidney development. The GFRα1 to 4 co-receptors are glycosyl-phosphatidylinositol-anchored proteins that selectively recognize and bind certain members of the GDNF family and associate with RET kinase to trigger intracellular signaling. For instance, GDNF preferentially binds to the GFRα1-RET heterodimer. The *RET* gene has been mapped to human chromosome 10q11.2 and is known to give rise to a transcript which is alternatively spliced to yield the short, middle, and long isoforms of RET, each containing an extracellular domain with a cadherin-related motif and a cysteine-rich region. When bound to GDNF, GFRα1 dimerizes with RET, and stimulates transphosphorylation of specific Tyr residues within the cytoplasmic domain of RET. The three RET isoforms have a number of Tyr residues in common, including those residing within the kinase domain and carboxy-terminus, though the long RET isoform contains an additional carboxy-terminal Tyr1096 residue. Once phosphorylated, these residues serve as scaffolding sites for signaling complexes. The conserved Tyr residues bind GRB10, PLCγ, and Shc, while Tyr1096 binds GRB2 specifically and links RET activation to the cell proliferation and survival pathways controlled by the Ras/Raf/MEK/ERK and PI3K/AKT pathways respectively. Underscoring the importance of Tyr1062, are studies that demonstrate that a point mutation within this codon significantly decreases the transforming activity of the RET protein. RET-mediated transformation results from various activating germline mutations in early-onset multiple endocrine neoplasia types 2A and 2B and late-onset familial medullary thyroid carcinoma. In addition, genetic rearrangements have been identified in papillary thyroid carcinoma. Chromosomal translocations involving the intracellular domain of *RET* have given rise to 10 known fusion proteins (RET/PTC1 -9 and RET/ELKS) prevalent in papillary thyroid carcinoma in a geographically distinct manner. These include translocations between *RET* and *H4*, *RIα*, *ELE1*, *RFG5*, *hTIF*, *RFG7*, *kinectin*, *RFG9*, and *ELKS*. The most common rearrangements, RET/PTC1 and RET/PTC3, involve inversions of the *H4* inv(10)(q11.2q21) and *ELE1* genes and account for 90% of all rearrangements in papillary thyroid carcinoma. Studies suggest that RET/PTC becomes ectopically localized to the cytoplasm where it activates STAT3 by phosphorylation of Tyr705. The constitutively active STAT3 promotes cellular transformation *via* stimulation of

cyclin-D1, *D2*, *D3*, and *bcl-XL* transcription. RET/PTC has also been implicated in the transcriptional upregulation of the osteopontin gene, resulting in an increase in the proliferative and invasive activity of cells that respond to autocrine stimulation by osteopontin. While RET/PTC rearrangements predominate in papillary thyroid carcinoma, germline mutations within *RET* are responsible for the onset of multiple endocrine neoplasia types 2A and 2B, and familial medullary thyroid carcinoma. Point mutations or base pair duplications of the *RET* gene have been reported in patients with multiple endocrine neoplasia 2A and familial medullary thyroid carcinoma. Missense mutations within *RET* have also been described in patients with multiple endocrine neoplasia 2A or 2B. Point mutations observed in multiple endocrine neoplasia 2A and familial medullary thyroid carcinoma, target the extracellular cysteine residues that normally contribute to intramolecular disulfide bonds, and promote RET dimerization. Formation of RET homodimers leads to its ligand-independent activation. On the other hand, RET mutations in multiple endocrine neoplasia 2B do not induce dimerization; rather, mutations target the catalytic core and may alter substrate specificity by inducing conformational changes in the region containing Tyr905, a conserved residue important for catalysis.

3.1.2 Cytoplasmic Protein-tyrosine Kinase Subfamily

ABL1/ABL2 The *ABL1* gene (chromosomal band 9q34.1), along with the closely related *ABL2* or *ARG* (Abl-related gene; chromosomal band 1q24-q25), belongs to the Abelson family of genes that encode prototypic non-receptor tyrosine kinases involved in various cellular processes. The *ABL1* gene product, c-Abl is a ubiquitously expressed protein that colocalizes with actin-based cytoskeletal structures in the cytoplasm, and binds chromatin when imported to the nucleus. These intermolecular interactions are mediated by the carboxy-terminal actin- and DNA-binding domains of c-Abl. The amino-terminus of c-Abl contains an SH-3 domain and an SH-2 domain. Autoinhibition of c-Abl is achieved by a novel variation on a familiar theme, and the details of this mechanism only recently became apparent when the crystal structure of the protein became available for examination. As in the case of the closely related Src kinases, the amino-terminus of the protein functions as an autoinhibitory ''Cap'' region preventing substrate docking with the kinase domain. However, this is not achieved by the binding of its SH-2 domain to a phosphotyrosine residue, as in other Src-like kinases. Rather, an amino-terminal myristate is responsible for binding to a hydrophobic pocket in the kinase domain that stabilizes an autoinhibited conformation. It is this distinction in the autoinhibitory mechanisms employed by c-Abl as compared with those of the other Src kinases that explains the ability of the drug imatinib (Gleevec®) to selectively inhibit the catalytic activity of c-Abl, but not that of c-Src. Targeted disruption of c-Abl in mice is characterized by lymphopenia, failure to thrive, and neonatal mortality. In the cytoplasm, c-Abl participates in the propagation of mitogenic signals via the Ras/Raf/MEK/ERK and PI3K/Akt pathways. This signaling is negatively regulated by the interactions of c-Abl with PSTPIP1, a PEST-type protein Tyr phosphatase that dephosphorylates c-Abl. c-Abl signaling in the nucleus results in a suppression of cell growth *via* the c-Abl-dependent transactivation of various proapoptotic genes. During the early G1

phase of the cell cycle, this nuclear activity of c-Abl is repressed due to its sequestration by the pocket protein Rb. Following an oncogenic and reciprocal chromosomal translocation, control of c-Abl activity is lost in cells, and this generates what has been termed the *Philadelphia chromosome*. This mutation is present in most cases of CML and many cases of ALL. Although similar translocations occur in CML and ALL, their c-Abl products are distinct, producing 210 kDa and 180 to 185 kDa proteins respectively. Both involve a t(9;22) (q34, q11) translocation of the *ABL* gene to the center of the *BCR* gene, producing a fused transcript that translates into a chimeric Bcr-Abl protein that is constitutively active. C-Abl activity is sustained by the loss of its autoinhibitory (myristoylated) amino-terminal tail and the dimerization triggered by the presence of coiled-coil domains within the amino-terminus of Bcr. Bcr-Abl dimerization, in turn, allows for the transphosphorylation of the fusion protein and activation of oncogenic signaling. The formation of Bcr-Abl homo-oligomers and hetero-oligomers with Bcr further promotes oncogenesis by localizing the protein in the cytosol and preventing DNA binding. The use of the small molecular tyrosine kinase inhibitor Gleevec® in the treatment of CML patients who are Bcr-Abl-positive has met with success, but drug resistance occurs frequently. Mutations of residues in or near the ATP-binding pocket of c-Abl prevent Imatinib binding and account for a majority of drug-resistant cases. The homologous *ARG* gene is involved in a similar translocation, but with a different fusion partner, Ets variant gene 6 (*ETV6/Tel*). ETV6/Tel is a member of the Ets family of transcription factors and is frequently found to be rearranged with a variety of translocation partners in human leukemias. This fusion protein contains the complete SH-3, SH-2, and PTK domains of ARG along with the helix–loop–helix oligomerization domain of ETV6/Tel. The translocation t(1;12)(q25;p13) causes malignancy in adult patients with acute myelogenous leukemia.

JAK-2 Janus kinase 2 (JAK-2) is a receptor-associated PTK essential for propagating certain cytokine induced signals. Located on human chromosome 9p24, the *JAK-2* gene encodes five JH domains, which are regions common to all members of the JAK kinase family and are sites of interaction between the protein kinase and its associated cytokine receptor. An amino-terminal JH-1 domain contains the kinase domain responsible for the phosphorylation of its preferred substrate; the Tyr, neutral, basic amino acid motif. Carboxy-terminal to the catalytic domain is a regulatory pseudokinase domain, referred to as the JH-2 domain. Normally, JAK-2 activity is cytokine-dependent. Interleukin-3 (IL-3), IL-5, and/or IL-6 interactions with cytokine receptors initiate receptor dimerization and the activating transphosphorylation of the constitutively associated JAK-2 proteins. Once active, JAK-2 phosphorylates Tyr residues on the carboxy-terminal region of cytokine receptors, providing binding sites for recruitment of STATs *via* their SH-2 domains. This in turn permits JAK-2 to phosphorylate STAT proteins, thereby promoting the disassociation of STATs from cytokine receptors, and their dimerization. When exported to the nucleus, dimeric STATs associate with the promoters of early response genes such as *c-fos*, *c-jun*, and *c-myc* and initiate transcription of cell-cycle regulatory genes such as *cyclin D1* and pro-survival genes such as

bcl-XL. Consequently, the constitutive activation of JAK-2 significantly enhances cell proliferation and survival. Deregulation of JAK-2 activity arises as a result of a somatic chromosomal translocation between the dimerization domain of the ETS-like transcription factor Tel and JAK-2. The resulting fusion protein contains the amino-terminal protein dimerization domain of Tel and carboxy-terminal JAK-2 catalytic domain (JH-1), and is able to form homodimers capable of transphosphorylating its binding partner, thus leading to constitutive activation. The Tel-JAK-2 fusion protein is ectopically localized within cells and may undergo unusual interactions with members of the early gene induction pathway in a cytokine-independent manner, thereby supporting cellular transformation. The presence of the *Tel-JAK-2* translocation and resulting transformation of hematopoietic cells underscore the importance of JAK-2 signaling in hematopoiesis. Examples of the Tel-JAK-2 driven transformation include cases of T-cell childhood acute lymphocytic leukemia, acute myeloid leukemia, acute lymphocytic leukemia, and atypical chronic myeloid leukemia. The finding that JAK-2 inhibition by a specific kinase blocker (i.e. AG-490) induces apoptosis of leukemic cells further supports the direct linkage between constitutive JAK-2 activation and malignant transformation. It is of note that while neither JAK-1 nor JAK-3 meets the criteria for inclusion in the cancer genome, both these cytoplasmic PTKs also signal to the nucleus *via* STATs and are overexpressed in various leukemias.

LCK The T-lymphocyte protein-tyrosine kinase (*LCK*) is a member of the Src-tyrosine kinase family and is located on the short arm of human chromosome 1 (1p34). LCK expression predominates in T cells, where its activity is crucial for normal T-cell development and activation. LCK is closely associated with the T-cell receptors (TCR) CD4 and CD8. LCK is a multidomain protein, typical of the Src kinases, including SH-3, SH-2, tyrosine kinase domains, and a unique domain responsible, among other things, for the membrane anchoring of LCK. During the process of acquiring adaptive immunity, T-cell activation is initiated by the binding of CD4 and CD8 to antigen-presenting cells *via* type I and type II glycoproteins of the major histocompatibility complex. The proximity of LCK to these activated TCRs allows for the transduction of signals responsible for the T-cell response, which includes the production of IL-2 and inositide (1,4,5) triphosphate. LCK activation requires autophosphorylation of Tyr394 and dephosphorylation of Tyr505, in the carboxy-terminal tail. The protein Tyr phosphatase CD45 regulates LCK activity in a bimodal fashion, not only by mediating Tyr505 dephosphorylation (enhanced activity) but also by dephosphorylation of Tyr394 (suppressed activity). LCK promotes T-cell activation by phosphorylating immunoreceptor Tyr-based activation motifs present within TCR complexes. When phosphorylated, these motifs enable recruitment of SH-2 domain–containing proteins (e.g. ZAP70) to the TCR. In addition, LCK phosphorylates the membrane–cytoskeleton linker protein ezrin to promote T-cell activation. In T cells, the LKC-dependent phosphorylation of the linker protein Shc also initiates mitogenic signaling *via* the Ras/Raf/MEK/ERK pathway. Because of the critical position occupied by LCK in the TCR signaling pathway, its necessarily transient activity is highly regulated through ubiquitination under the control of the Cbl ubiquitin ligase. LCK mutations resulting in constitutive

autophosphorylation and/or deregulated catalytic function have been described in T-cell leukemia, where they contribute to the oncogenic potential of this kinase. Insertion of the tripeptide QKP between the cytosolic SH-2 and kinase domains may also enhance catalytic function by disrupting the normal repressive interaction of its SH-2 domain with its catalytic site. Three other recorded mutations, resulting in a substitution within the region critical for interaction between LCK and CD4 and two alternative substitutions within the kinase domain, may result in a GOF for LCK. In addition to these mutations, a chromosomal translocation (t(1;7)(p34;q34)) has been observed in T-cell acute lymphoblastic leukemia, resulting in an oncogenic fusion protein (i.e. βTCR:LCK) that contains the βTCR enhancer region and the 5′ promoter region of LCK. In the case of the βTCR:LCK fusion, a GOF would result from an alleviation of transcriptional repression by the βTCR enhancer region.

3.2 Protein-serine/Threonine Kinase Family

3.2.1 Tyrosine Kinase-like Subfamily

BRAF BRAF is discussed above in Sect. 2.2.

3.2.2 Homologs of Yeast Sterile 7, Sterile 11, Sterile 20 Kinase Subfamily

JNKK The c-Jun terminal kinase–kinase (*JNKK*) gene is located on human chromosome 17p11. This oncogene encodes a dual specificity kinase catalyzing Thr180 and Tyr182 phosphorylation of p38 MAP kinase and JNK1, 2, and 3 in response to environmental stress, including changes in cellular osmolarity. The functional consequences of JNKK signaling are cell-type-, environment-, and stimulus-specific. Regulation of JNKK occurs upstream of the kinase as a result of the ubiquitin-mediated degradation of MAPK kinase–kinase (MEKK1). Ubiquitination prevents phosphorylation of JNKK by MEKK1 and abrogates downstream activation of JNK. JNK activation requires stable complex formation between JNKK and JNK. The amino-terminal region of JNKK facilitates this interaction as it codes for a conserved MAP kinase-docking site (D-domain). JNKK is able to modulate JNK signaling to AP-1 transcription factors by competitive sequestration of JNK *via* D-domain interactions. In a classic response to UV irradiation, JNKK mediated activation of JNK results in apoptosis through a p53-dependent mechanism. Downregulation of JNKK or its downstream signaling components provides cells with a growth advantage. Moreover, a loss of JNKK expression has been observed in various cancers, including prostate cancer. An overall *JNKK* mutation rate of ~5% has been observed in various types of tumors. The mutations include two nonsense mutations, five missense mutations, and one splice site mutation. Not surprisingly, these mutations generally serve to inactivate JNKK signaling. In keeping with its tumor suppressor classification, the *JNKK* gene is a known target for homozygous deletions in pancreatic adenocarcinomas, biliary adenocarcinomas, and breast carcinomas.

3.2.3 Calcium/Calmodulin-dependent Protein Kinase Subfamily

PIM-1 A common site for proviral integration of the moloney murine leukemia virus (PIM) in mice encodes the *PIM-1* gene. The Ser/Thr kinase PIM-1 is the product of this gene, which is located

on the p12 segment of human chromosome 6. In addition to PIM-1, PIM-2 and PIM-3 make up the PIM family of kinases and may serve redundant functions as observed in PIM-1-deficient mice, where compensation for the loss of *PIM-1* was evident. PIM-1 functions to promote hematopoiesis in response to growth factors such as IL-2 and IL-3 and its expression is confined, throughout fetal development, to hematopoietic sites within the liver and spleen, as well as within the thymus, lymph-nodes, and testis. High expression of PIM-1 has also been observed in myeloid cell and B-cell lines. PIM-1 has been characterized as a 33-kDa cytoplasmic protein, though recent studies have revealed that its nuclear localization is crucial for its antiapoptotic function in Burkitt's lymphoma. Upregulation of PIM-1 has been implicated in BCR/ABL mediated leukemogenesis where it acts downstream of STAT5 to confer protection from apoptosis and promote cell-cycle progression. PIM-1 overexpression has also been shown to positively influence a variety of human leukemias, though overexpression alone is not sufficient for cellular transformation, and cooperation between PIM-1 and c-myc is often observed during this process. The identification of a breakpoint region on chromosome 6 has raised the possibility of a translocation between *PIM-1* and the proto-oncogene *c-ABL* (t(6;9)(p21; q33)) in some cases of myeloid leukemia. In response to cytokines and various mitogens, *PIM-1* expression is induced *via* the JAK/STAT5 and MAP kinase pathways and its activity may be modulated through a series of autophosphorylation events. With the exception of Etk, which promotes the activation of PIM-1 *via* phosphorylation of Tyr218, upstream kinase regulators of PIM-1 have not been identified. Recent studies show that phosphorylation of the nuclear mitotic apparatus protein by PIM-1 facilitates interactions between this protein, the heterochromatic protein-1β, and the spindle proteins dynein and dynactin, which are crucial for mitosis. Furthermore, PIM-1 alleviates transcriptional repression by directly phosphorylating HPI, a member of the transcriptional repression machinery, thereby regulating chromatin structure. Other putative substrates of PIM-1 include p100, a co-activator of the transcription factor c-myb, the cell-cycle phosphatase Cdc25A, and the cyclin-dependent kinase inhibitor $p21^{cip1}$. It is evident that PIM-1 regulates the activity of many proteins that have the potential to promote tumor growth and, as expected, its expression is tightly regulated *via* transcriptional and translational mechanisms. The presence of dyad symmetry elements enables the *PIM-1* gene to form stem loop structures, and to block transcriptional elongation in the absence of appropriate stimuli. Another regulatory element is present in the form of an A/U rich region within the 3′-unstranslated region of PIM-1 mRNA. This region promotes RNA instability, which can be overcome in the presence of certain cytokines and mitogens. Translation of the PIM-1 message is regulated by the presence of a 5′-untranslated region containing an internal ribosomal entry site. PIM-1 activity may also be regulated *via* autophosphorylation, while its turnover rate is dependent upon ubiquitination. In the event of deregulated PIM-1 expression, oncogenesis is most likely facilitated by the PIM-1-dependent stimulation of cell-cycle progression and mitosis.

STK11 Serine–threonine kinase 11 (STK11), also known as LKB1, is a crucial regulator of cellular metabolism and polarity. This cytoplasmic kinase is ubiquitously expressed in human tissues and exhibits

catalytic activity only in the presence of its binding partner STRAD (STE20-related adapter). As STRAD lacks intrinsic kinase activity, the association of the pseudokinase domain of STRAD with the kinase domain of STK11 is postulated to result in intermolecular interactions capable of stimulating the STK11 catalytic core. In the cytoplasm, the association of STK11 with STRAD gives rise to a series of STK11 autophosphorylation events and results in the phosphorylation of STRAD. Induction of cell polarity by STK11 may result from its association with the Ser/Thr kinase PAR1. This leads to destabilization and polarized localization of microtubules. STK11 also plays a role in axis induction during development by stimulating the Wnt signaling pathway. The tumor suppressor activity of STK11 is mediated by the ataxia-telangiectasia mutated kinase (ATM, see below). In response to the cellular stress caused by ATP depletion, STK11 directly phosphorylates Thr172 of the AMP-activated kinase. This results in the downregulation of ATP-consuming processes, such as the translational activity mediated by the mammalian target of rapamycin, and upregulation of ATP-producing processes such as glucose uptake. Therefore, the loss of STK11 expression, observed in various carcinomas, offers cells a distinct growth advantage by removing the inhibition normally placed on protein synthesis and mitogenesis. The tumor suppression activity of STK11 makes it a target for inactivating mutations such as those observed in patients with the hereditary Peutz-Jeghers syndrome. Indeed, the *STK11* gene was mapped to region p13.3 of human chromosome 19 – a site susceptible to germline mutations in patients with Peutz-Jeghers syndrome. In addition to the formation of benign intestinal hamartomatus polyps, individuals with Peutz-Jeghers syndrome exhibit a predisposition toward gastrointestinal, pancreatic, ovarian, testicular, uterine, and breast carcinomas. Studies have identified various deviations of the wild-type STK11 transcript. These are caused by translational frameshift insertions or deletions, nonsense mutations, missense mutations, and disruption of STK11 mRNA splicing through exonal splice site mutations. The functional consequence of these mutations is the generation of an inactive STK11 protein. Germinal *STK11* mutations are often accompanied by somatic mutations. Somatic mutations leading to homozygous deletion of *STK11* or *STK11* truncations have also been reported in patients with non-Peutz-Jeghers syndrome related pancreatic cancer, mucinous minimal deviation adenocarcinoma of the uterine cervix, lung adenocarcinoma, and malignant melanoma. In general, *STK11* mutations affect the biological activity of STK11 by one of two common means. Large truncations or targeted mutations of invariant residues within the STK11 kinase domain destroy its ability to bind ATP and catalyze phosphotransfer. The SL26 mutant present in some cases of Peutz-Jeghers syndrome does not affect kinase activity; rather it promotes the loss of cytoplasmic retention, which is accompanied by nuclear localization of STK11. It is hypothesized that nuclear localization results from the inability of the SL26 mutant to interact with its cytoplasmic substrates and thereby remain in the cytoplasm. Nuclear localization also leads to silencing of STK11 signaling because of the lack of substrates and activating factors. Paradoxically, owing to a marked increase in the AMP/ATP ratio, cells with loss of STK11 expression are rendered more susceptible to cell death caused by agents such as the

AMP analog AICAR. This response may represent a unique therapeutic opportunity for those patients whose carcinomas exhibit a loss of STK11 activity.

3.2.4 Containing Pka, Pkg, Pkc Subfamilies

AKT2 The *AKT2* gene, located at 9q13.1-q13.2, produces a phosphoinositide-dependent Ser/Thr kinase, crucial for regulating cellular events including apoptosis, differentiation, proliferation, and metabolism. The gene product of AKT2, also referred to as protein kinase B beta (PKB-β), is a broadly expressed protein containing a single 3-phosphoinositide-binding pleckstrin homology (PH) domain at its amino terminal. Adjacent to this pleckstrin homology domain is the kinase domain, followed by a carboxy-terminal regulatory domain. The AKT isoforms (AKT1 and AKT2) function downstream of various RTKs, and the biogenesis of an active AKT requires the sequential recruitment of the inactive protein to the plasma membrane followed by the transphosphorylation of a conserved Thr residue within the activation loop (Thr308 in AKT1 and Thr306 in AKT2) and Ser residue within a carboxy-terminal hydrophobic motif (Ser473 in AKT1 and Ser474 in AKT2). AKT is recruited to the plasma membrane through the binding of its amino-terminal PH domain to phosphatidylinositol-3, 4, 5-triphosphate (PIP_3), a lipid product of PI3K. This protein−-lipid interaction is tightly controlled by the lipid phosphatase *PTEN* (phosphatase and tensin homolog), which is also a cancer (tumor) suppressor gene that undergoes both somatic and germline inactivating mutations. By anchoring AKT to the membrane lipid bilayer, PIP_3 alters the conformation of the AKT kinase domain and exposes the activation loop phosphorylation site to PDK1. Following this ''priming'' step, AKT is phosphorylated on its hydrophobic motif by a yet-to-be-identified protein Ser/Thr kinase. Integrin-linked kinase was shown to be essential for this final step in the maturation of AKT, but whether this kinase is directly responsible for AKT phosphorylation remains unresolved. The authentic AKT hydrophobic motif kinase may be the DNA-dependent protein kinase. Good evidence for this has recently been presented, but has not yet been confirmed. Once activated, AKT is capable of enhancing cellular proliferation and the generation of survival signals through some of the pathways and effector molecules included in Figure. 1. *AKT2* was included in the census of cancer genes because of its amplification in ovarian and pancreatic cancers. The region that is amplified in ovarian carcinomas (19q13.1-q13.2) spans the entire *AKT2* gene. However, no activating mutations have been documented for this kinase in cancer and, therefore, tumors in which *AKT2* has been amplified may not be responsive to small-molecule inhibitors of kinase activity. Depending on the genetic profile presented by a given patient, other oncogenes might contribute to the transforming activity of AKT2. For example, the coexistence of an *AKT2* amplification and loss-of-function mutation in *PTEN* would allow an enhancement of AKT2 signaling in the presence of endogenous growth factors. The human prostate epithelial cancer cell line LNCaP harbors such a *PTEN* mutation and possesses constitutive AKT kinase activity. Another interesting candidate in ovarian cancer is *SEI-1*. *SEI-1* is located in a genetic region of chromosome 19q13.1-q13.2, neighboring *AKT2*. This genetic region is coamplified along with *AKT2* in a subset of ovarian cancer

cell lines. The *SEI-1* gene encodes a CDK4-binding protein, which renders the activity of cyclin D/CDK4 complexes resistant to the inhibitory effect of $p16^{INK4a}$. Given the proliferation-related functions of AKT2 and SEI-1, it is possible that both gene amplifications at chromosome 19 have the potential to advance the growth of certain ovarian tumors.

3.2.5 Containing Cdk, Mapk, Gsk3, Clk Subfamilies

CDK4 and the INK4 inhibitors The human cyclin-dependent kinase 4 (*CDK4*) gene is located at chromosome 12q14 and encodes a small (303 amino acid) cell-cycle regulatory protein Ser/Thr kinase essential for coordinating the cell's progression through the early growth (G1) phase of the cell cycle. CDK4 is activated by the binding of D-type cyclins (which impart basal activity to the kinase) and, by phosphorylation (which fully activates the kinase). When active, CDK4 interferes with the tumor suppressor activity of the retinoblastoma protein Rb and its homologs. CDK4 is inactivated by the binding of the INK4 family of CDK inhibitors. G1 progression depends on extracellular mitogenic signals that upregulate cyclin D expression, committing the cell to another round of cell division. INK4 proteins bind monomeric CDK4, preventing its stable interaction with cyclin D. They also bind the cyclin D – CDK4 complex, forming an inactive ternary complex. There are four INK4 proteins ($P16^{INK4a}$, $P15^{INK4b}$, $P18^{INK4c}$, and $P19^{INK4d}$), all of which possess ankyrin repeats involved in binding CDK4. The binding of these proteins substantially alters the conformation of the CDK4 ATP-binding site and renders the kinase inactive. Mutations leading to a loss of control over the CDK4/INK4/Rb pathway are among the most common in human cancer. CDK4 is often amplified and overexpressed in glioblastoma (50%), uterine cervical carcinoma (26%), breast carcinoma (16%), and osteosarcoma (16%). In addition, a germline arginine-to-cysteine substitution at codon 24 has been reported in some cases of melanoma. This mutation contributes to malignant transformation by preventing the interaction between $p16^{INK4a}$ and CDK4, but is rarely encountered in other human neoplasms. More common are mutations in the binding region of the *INK4* genes, lowering the affinity of the INK4 proteins for CDK4. In the case of $p16^{INK4a}$, such mutations occur frequently in leukemia (58%), bladder carcinoma (50%), glioma (35%), nasopharyngeal carcinoma (35%), and pancreatic cancer (21%). Promoter methylation is also a common mechanism of inactivation of the *INK4* genes in cancer.

3.2.6 Phosphatidylinositol Kinase (Pik)-Related Subfamily

ATM The human tumor suppressor gene ataxia-telangiectasia mutated (*ATM*) is located on chromosome 11q22-q23 and is frequently mutated in a rare autosomal recessive disorder causing neuronal degeneration, immunologic deficiency, radiosensitivity, and cancer predisposition. Over one-third of ataxia-telangiectasia patients develop lymphoid cancers including non-Hodgkin's lymphoma, Hodgkin's lymphoma, and other leukemias. The *ATM* gene encodes a large (3056 amino acid) nuclear protein that is expressed in testis, spleen, and thymus of adult mice and plays a critical role in maintaining genetic stability in response to DNA damage. ATM is a member of the recently identified PIK-related subfamily that phosphorylates Ser/Thr residues, rather

than lipids. All members contain a conserved carboxy-terminal catalytic domain, referred to as the PI-kinase domain, and a novel amino-terminal FAT (FRAP, ATM, and TRRAP) domain that possibly regulates the conformation of the PI-kinase domain. Structurally, ATM is composed of two regions referred to as the *head* and an *arm*. Three-dimensional reconstructions of ATM bound to DNA suggest that the kinase uses its arm to clamp around the double helix. Whether this protein–DNA interaction is required for the ATM-dependent repair of double-strand breaks is not known. ATM activation in response to DNA double-strand breaks is rapidly triggered following ionizing radiation functions to arrest the cell-cycle progression of damaged cells in G1, S, or G2. The G1/S checkpoint is activated through the induction of p53. ATM positively regulates the p53 pathway by increasing the half-life of the p53 protein, either by directly phosphorylating Ser15, or indirectly through activation of other kinases such as Chk2 and c-Abl. ATM, Chk2, and c-Abl are all capable of phosphorylating p53, thus stabilizing the later protein by interfering with its binding to the p53 regulatory protein, murine double minute 2. In addition to regulating the G1/S checkpoint, ATM engages the S and G2/M checkpoints in response to ionizing radiation. It triggers the G2/M checkpoint by Chk2-mediated phosphorylation of Ser216 on Cdc25C, thereby promoting the binding of 14-3-3 proteins. The Cdc25C/14-3-3 complex is then exported from the nucleus, preventing Cdc25C from activating the nuclear Cdc2/cyclinB complex required for mitosis. In a similar fashion, ATM controls the S-phase checkpoint through the Chk2-dependent phosphorylation of Cdc25A Ser123. This leads to Cdc25A degradation. Most of the ATM mutations associated with cancer are derived from large deletions, causing protein truncations that inactivate the kinase. Other inactivating mutations are represented by missense mutations (e.g. L1420F) or small in-frame deletions/insertions. This loss of ATM function is thought to predispose to cancer by increasing genetic instability.

Keywords

Cross-Link
Covalent bond between two macromolecular moieties, usually formed when two macromolecular free radicals recombine.

DNA Strand Breakage
Event induced by certain kinds of chemical damage, through free-radical processes involving the DNA molecule but also through the action of enzymes that try to repair the DNA damage.

Free Radical
Chemical species that is highly reactive because it possesses an unpaired electron.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 7

Heteroatom
Atom in a molecule of an organic compound that is neither a carbon nor a hydrogen atom.

Ionizing Radiation
Energetic photons (X rays, γ-rays) and energetic particles (β-rays, fast electrons from electron accelerators, positrons, α-rays and other fast-moving ions, neutrons) that cause multiple ionization events along their trajectory through matter.

Peroxyl Radical
Generated by addition of dioxygen to a free radical.

Pulse Radiolysis
Technique for studying the kinetics of the chemical reactions of short-lived intermediates: for example, the aqueous solution of a substrate is exposed to a short (nanoseconds-to-microseconds range) burst of high-energy electrons from an electron accelerator.

Radical Ion
Free radical with a positive or negative charge.

Ionizing radiation represents an important risk factor to the living organism. It has always been part of the natural environment, hut it is also now a technological phenomenon, lending added urgency to the study of its effects on living matter. It has been established that the most sensitive target in the living cell is the DNA, which undergoes radiation damage through free-radical processes. This effect has two practical aspects beyond its purely scientific interest: to assess the radiation risk with a view to minimize it, perhaps by chemical means, and to apply ionizing radiation selectively for therapeutic purposes (e.g. in cancer treatment). These goals will not be optimally achieved without adequate knowledge of the chemical processes that ionizing radiation sets in train in DNA.

1 Energy Absorption

Absorption of ionizing radiation by matter leads to the formation of radical cations and electrons (reaction 1) and electronically excited molecules (reaction 2).

$$\mathrm{M} + \text{ionizing radiation} \longrightarrow \mathrm{M}^{\bullet+} + \mathrm{e}^- \quad (1)$$

$$\mathrm{M} + \text{ionizing radiation} \longrightarrow \mathrm{M}* \quad (2)$$

Energy deposition is inhomogeneous. In the case of sparsely ionizing radiation

(e.g. γ-rays or high-energy electrons), the average distance between two regions of energy deposition is about 200 Å in matter of about unit density (i.e. in aqueous media). With densely ionizing radiation (e.g. α-particles) these regions, which are called *spurs* and are centered on the location of a primary ionization event, strongly overlap to form a continuous ionization track. The rate of energy deposition is proportional to the electron density. In the living cell, about 70% of the energy is absorbed by the water and about 30% by the organic matter and other solutes.

The radiolysis of water leads to the formation of $^{\bullet}OH$ radicals, solvated electrons, and $H^{\bullet}$ atoms. The water radical cation readily transfers a proton to the neighboring water molecules, thereby yielding an $^{\bullet}OH$ radical (reaction 3), and the electron becomes solvated (reaction 4). Electronically excited water may decompose into $^{\bullet}OH$ and $H^{\bullet}$ (reaction 5).

$$H_2O^{\bullet+} \longrightarrow {}^{\bullet}OH + H^{+} \qquad (3)$$

$$e^{-} + nH_2O \longrightarrow e^{-}_{aq} \qquad (4)$$

$$H_2O* \longrightarrow H^{\bullet} + {}^{\bullet}OH \qquad (5)$$

For sparsely ionizing radiation, the radiation-chemical yields, or G values, (The G value is expressed in molecules per 100 eV, which corresponds to 1.037×10^{-7} mol J^{-1}.) are $G(^{\bullet}OH) = 2.8 \times 10^{-7}$ mol J^{-1}, $G(e^{-}_{aq}) = 2.7 \times 10^{-7}$ mol J^{-1}, $G(H^{\bullet}) = 0.6 \times 10^{-7}$ mol J^{-1}. In the spurs, some radical combination occurs yielding the "molecular products" H_2 and H_2O_2 ($G(H_2) = 0.45 \times 10^{-7}$ mol J^{-1}, $G(H_2O_2) = 0.8 \times 10^{-7}$ mol J^{-1}). The water-derived radicals are all highly reactive. Hence, their formation and reactions cause an important part, possibly the major part, of the radiation damage to the living cell.

2 Radiation-induced DNA Lesions

Ionizing radiation is absorbed by the various cell components with practically equal probability. This is in contrast with UV radiation, which is predominantly absorbed by the cellular nucleic acids. While the mechanism of inactivation in the two cases (UV vs ionizing radiation) is quite different, DNA again is by far the most sensitive target to damage induced by ionizing radiation. Subionization UV radiation mainly causes base dimerizations (e.g. formation of thymine dimers at 260 nm) with barely any strand breakage. Ionizing radiation produces very little of this type of damage but causes, characteristically, DNA strand breakage. Ionizing radiation base damage is largely due to free-radical reactions, including those caused by the $^{\bullet}OH$ radicals generated by the radiation absorbed in the aqueous medium surrounding the DNA. In this way, a considerable number of different kinds of damage arise whose products one may group into the following categories:

Altered bases

Altered sugar moiety
- DNA strand break
- Release of unaltered bases

Cross-links
- DNA-DNA
- DNA-protein

Apart from phosphate-ester bond cleavage, which constitutes a strand break, the phosphate moiety as such is not modified. It is important to realize that the cluster-type energy deposition of the ionizing radiation will cause some of the damaging events also to appear in clusters; that is, there is a considerable likelihood

that, especially in double-stranded DNA, one damaged site will be close to another, or even to several others. These "clustered lesions" have also been termed *locally multiply damaged sites* (LMDS). They may involve damaged bases and one or two single-strand breaks. Two opposite single-strand breaks will result in a DNA double-strand break.

In the living cell, the DNA is surrounded not only by proteins (e.g. histones in eukaryotic cells) but also by a high concentration of low molecular weight organic material, among others the thiol glutathione. These react very efficiently (i.e. at practically diffusion-controlled rates) with the water-derived radicals ($^{\bullet}OH$, e^-_{aq}, $H^{\bullet}$) formed in the aqueous surrounding of DNA. Hence, these are effectively scavenged, and so the DNA is largely protected against, say, $^{\bullet}OH$-attack. Only $^{\bullet}OH$ radicals generated in the close vicinity of DNA stand some chance of reacting with and hence doing damage to the genetic material.

3 Reaction of DNA Radicals

Damage by ionizing radiation, induced either by the direct effect or by water radicals, will result in DNA radicals; these are the precursors of the final (nonradical) damage at the product stage. The thiol glutathione (GSH), which is present in living cells at comparatively high concentrations (approaching 10^{-2} mol dm^{-3}) can react with the DNA radicals ($R^{\bullet}$) by H-transfer (reaction 6).

$$R^{\bullet} + GSH \longrightarrow RH + GS^{\bullet} \qquad (6)$$

This reaction is thermodynamically slightly favored because the S−H bond is relatively weak. Recently, it has been realized that the peptide C−H bond in proteins is even somewhat lower, but it has not yet been established whether proteins attached to DNA (e.g. histones) reduce $^{\bullet}OH$-induced damage not only by scavenging $^{\bullet}OH$ radicals but also by H-donation to a DNA radical.

In competition with this H-donation reaction, dioxygen can add to the DNA radicals, thereby forming the corresponding peroxyl radicals (reaction 7).

$$R^{\bullet} + O_2 \longrightarrow ROO^{\bullet} \qquad (7)$$

These peroxyl radicals give rise to the final products. Some of the peroxyl radicals are capable of eliminating $HO_2^{\bullet}/O_2^{\bullet-}$, but the major part will decay bimolecularly (reaction 8).

$$2ROO^{\bullet} \longrightarrow \text{products} \qquad (8)$$

Low-molecular–weight peroxyl radicals often terminate at dose to diffusion-controlled rates. In high-molecular–weight material such as DNA, the diffusion of radical-bearing segments is considerably restricted. Hence, they may persist for relatively long times and may undergo reactions other than reaction (8) or the elimination of $HO_2^{\bullet}/O_2^{\bullet-}$.

The reaction of the primary DNA radicals with glutathione is usually termed *chemical repair*. However, a repair in the true sense is achieved only if the radical site to be repaired has been created by H-abstraction (e.g. reaction 9).

$$RH + {}^{\bullet}OH \longrightarrow R^{\bullet} + H_2O \qquad (9)$$

In DNA, such sites are present only at the sugar moiety or at the methyl group of thymine. For the most part, $^{\bullet}OH$ reacts by addition to a C=C or C=N bond (e.g. reaction 10). Subsequent "repair" by H-donation leads to the formation of

a hydrate (reaction 11) rather than the original molecule.

$$R_2C{=}CR_2 + {}^{\bullet}OH \longrightarrow HOCR_2{-}CR_2^{\bullet} \quad (10)$$

$$HOCR_2{-}CR_2^{\bullet} + GSH \longrightarrow HOCR_2{-}CHR_2 + GS^{\bullet} \quad (11)$$

Apparently, the cellular enzymatic repair system can cope with this kind of damage much better than the kind resulting from peroxyl radical reactions (cf the ''oxygen effect'' in radiobiology).

4 Model Studies

Although the chemical nature of some kinds of base damage has been studied *in vivo*, most of our knowledge of radiation-induced DNA damage is derived from model studies. Electron spin resonance studies for the identification of radicals have mainly been carried out in the solid state at low temperatures. In contrast, practically all product and kinetic (pulse radiolysis) studies have been done in dilute aqueous solutions. Thus, they reflect mostly the indirect effect.

In the direct effect, radical cations (and electrons) are the species primarily produced (reaction 1). To mimic this reaction and to study the fate of radical cations in aqueous solutions, photoionization with a laser (monophotonic at $\lambda = 193$ nm or biphotonic at $\lambda = 248$ nm) or electron transfer to photoexcited quinones (Q) were used with some advantage (e.g. reaction 12).

$$Q* + \text{nucleobase} \longrightarrow Q^{\bullet-} + \text{nucleobase}^{\bullet+} \quad (12)$$

The nucleobase radical cations are strong acids. Quick deprotonation ensues at a heteroatom, but in thymine, deprotonation can eventually materialize at the exocyclic methyl group carbon, in competition with a nucleophilic addition of water to the carbon 6 position. Although after deprotonation the heteroatom-centered radical predominates, the radical cation in near-neutral media is always present at low ''equilibrium'' concentrations. In contrast to the situation at the heteroatom, deprotonation at the methyl position is practically irreversible under these conditions.

Nucleobase cations are strong oxidants (for a sugar-derived radical cation see below), and in DNA those derived from thymine, cytosine, and adenine may oxidize a neighboring guanine (G), the nucleobase with the lowest reduction potential. Hole transfer through DNA is now a well-documented process. The ultimate sinks of the hole are GG doublets and, even better, GGG triplets whose reduction potentials are substantially lower than that of a single G. Mechanistically, this hole transfer can be described by an incoherent hopping process involving quantum-mechanical channels.

The electrons formed in the ionization process are readily scavenged by the nucleobases (a diffusion-controlled reaction). The radical anions thus formed are strong bases. Hence, it is not surprising that those derived from adenine, guanine, and cytosine are protonated by water on the submicrosecond timescale. The thymine radical anion has a pK_b value of about 7.0, and therefore is much longer lived than the other radical anions.

Most of these radical anions (and to a lesser extent their heteroatom-protonated forms) have pronounced reducing properties; that is, they are capable of retransferring the electron to an oxidant.

However, they are metastable species with respect to ultimate conversion into carbon-protonated intermediates (e.g. in thymine, the final protonation site is C-6). These radicals no longer have reducing properties.

This sequence of events also has a bearing on the reactions of the radical anions with dioxygen. For example, the thymine radical anion and its heteroatom-protonated form react with dioxygen by forming $O_2^{\bullet -}/HO_2^{\bullet}$ thereby regenerating the nucleobase, while in the reaction of dioxygen with the C-6-protonated radical anion, the thymine molecule is destroyed.

Besides the formation of nucleobase radical cations (on account of the direct effect) and radical anions (by e^- attachment), one must consider the reactions of the $^{\bullet}OH$ radical as a major contributor to radiation-induced DNA damage. It mostly adds to the double bonds of the nucleobases, but it also abstracts H atoms from the sugar moiety and the methyl group in thymine.

For the investigation of $^{\bullet}OH$-induced reactions in isolation, in radiation-chemical experiments it is standard practice to convert e_{aq}^- (from reaction 4) into $^{\bullet}OH$ by saturating the solution to be irradiated with nitrous oxide (reaction 13).

$$e_{aq}^- + N_2O \longrightarrow {}^{\bullet}OH + N_2 + OH^- \qquad (13)$$

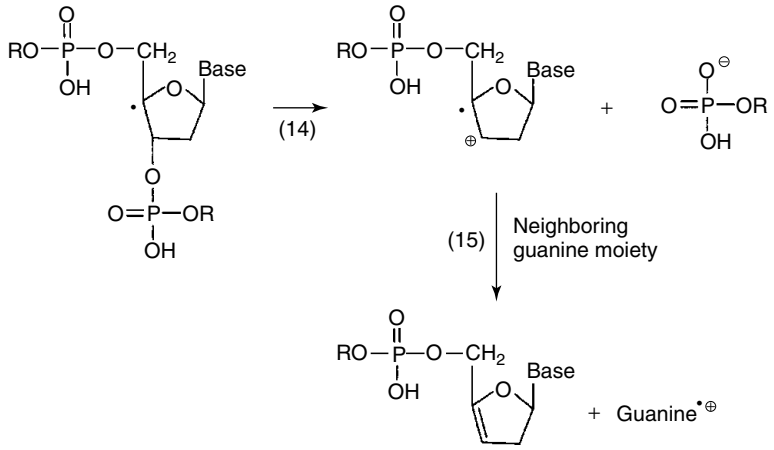
As a result, the radical species now consist of 90% $^{\bullet}OH$ and 10% $H^{\bullet}$; that is, the observed reactions and their products are dominated by the effects of the $^{\bullet}OH$ radical. In the pyrimidines, $^{\bullet}OH$-addition to the C-5 position yields a reducing radical, while an addition to the C-6 position yields a radical with oxidizing properties. These properties can be defined using suitable redox probes. The pulse radiolysis technique has allowed the characterization of these radicals and the determination of their yields. In the case of the purines, the redox titration technique is not as straightforward, and the assignment of the sites of $^{\bullet}OH$-addition is complicated by rapid ring-opening and water elimination reactions.

Our present knowledge of pyrimidine free-radical chemistry (in particular, uracil and thymine, their methyl derivatives as well as their nucleosides) is much more extensive than that of the purines. It is obvious from the published data that only a fraction of the primary purine $^{\bullet}OH$-adduct radicals have shown up in the form of products. Considerable effort will be required to bring the purine (and cytosine) free-radical chemistry to a satisfactory level of understanding. This situation is also reflected in the determination of the base product yields from irradiated DNA, where a considerable deficit in the product yields (related to the primary $^{\bullet}OH$ radical yield) is observed.

5 DNA Strand Breakage and Cross-linking

Solvated electrons do not cause DNA strand breakage, but $^{\bullet}OH$ radicals do. In competition with addition to the nucleobases, they also abstract H atoms from the sugar moiety. This has two possible consequences: in the subsequent reactions a strand break is induced and an unaltered base is released, or base release occurs without giving rise to strand breakage. Hence, base release always predominates somewhat over strand breakage. A number of altered sugars that are related to these processes have been identified, both in the absence and in the presence of dioxygen. On the basis of detailed model studies, the reactions and their kinetics

leading to strand breakage in the absence of dioxygen are fairly well understood. The primary step is the abstraction of the H atom at C-4′:



a damaged sugar remains linked to the phosphate group. Enzymatically speaking, this is a ''dirty'' end group. Details of the mechanism of DNA strand breakage under conditions of oxygenation are less well understood, but some of the relevant sugar lesions have been detected. Model systems (ribose 5-phosphate) indicate that under these conditions C-5′ should be an additional site of attack and, in analogy, one would expect (no experimental evidence yet) the C-3′ peroxyl radical also to be a potential precursor for strand breakage.

This radical then eliminates a neighboring phosphate (linked to a fragment of the DNA strand) (reaction 14), leaving behind a radical cation. This radical cation has oxidizing properties and can oxidize a neighboring guanine moiety (reaction 15) with the consequence of hole migration through DNA (see above). In competition, the sugar radical cation reacts with water, either at the position that has eliminated the phosphate, or at C-4′. In the former case, the other phosphate function may be eliminated by the same mechanism; in double-stranded DNA, this sequence of events produces a clean gap in the affected strand (the end groups of the two fragments are phosphate groups) with the loss of some information because of the disappearance of the damaged nucleoside. In the latter case, the base is also lost, but additionally at the end of one of the fragment strands,

So far, sugar damage has been discussed only in terms of $^{\bullet}OH$ radicals attacking this moiety. A contribution of the direct effect (ionization of the sugar moiety and the phosphate groups) must also be considered, but experimental evidence is not yet available. However, there is another interesting aspect. In polynucleotides such as poly(U) and poly(C), there is convincing evidence that base radicals are the major precursors of the sugar radicals that lead to strand breakage and the release of an

unmodified base at the site of the damaged sugar. It is less clear whether such a radical transfer from the base to the sugar moiety can also occur in DNA.

In mammalian cells, DNA double-strand breaks are observed alongside single-strand breaks approximately in the ratio of 1 : 25. This poses the question of how these double-strand breaks are formed. It has been argued here that they result from clustered lesions. In the literature, an additional one-hit route has been suggested that involves a radical transfer from the already broken strand to the sugar moiety of the opposite strand, followed by breakage of this strand.

Carbon-centered radicals are known to add to the C=C bonds of nucleobases. Such reactions, as well as radical–radical combination reactions involving macroradicals, in principle allow the formation of DNA–protein and DNA–DNA cross-links. In special cases, such products have been observed with biological material, albeit in yields considerably lower than DNA double-strand breaks.

Keywords

Dipole–dipole Interaction
Arises from Coulomb or magnetic fields mutually induced by electrostatic or magnetic dipoles respectively.

Exchange Interaction
Originates from inter- or intramolecular interaction between electrons due to their quantum mechanical delocalization (e.g. overlap of orbitals populated with the electrons).

Label
A compound that binds covalently to an object under study and whose properties enable monitoring by appropriate physical methods.

Probe
A compound that either adds on non-covalently or diffuses freely in the medium.

Spin
The intrinsic angular momentum of an unpaired electron that induces magnetic momentum.

In solving problems of molecular biology, molecular biophysics and biochemistry of proteins, nuclear acids, and biomembranes, it is necessary to investigate molecular dynamics properties of biological objects and spatial disposition of their individual parts. One must also know the depth of immersion of definite centers in a biological matrix, that is, the availability of enzyme sites to substrates, distance of electron tunneling between a donor and an acceptor group, position of a biophysical label in a membrane and in a protein globule, distribution of the electrostatic field around molecules, and so on. The biophysical labeling approach consists, in principle, of

the modification of chosen sites of an object of interest by special compounds (labels and probes) whose properties make it possible to trace the state of the biological matrix by appropriate physical methods. Four types of compound are most often used as labels and probes: (1) centers with unpaired electrons, spins (stable nitroxide radicals and paramagnetic metal complexes); (2) fluorescent and phosphorescent chromophores; (3) electron-scattering groups of heavy atoms (e.g. polygold or polymercury compounds); and (4) Mössbauer atoms (e.g. ^{57}Fe), which give the nuclear γ-resonance spectra. Three types of problems can be solved by means of labeling technique on a molecular level: (1) recording of conformational changes in proteins, enzymes, membranes, and other structures; (2) the investigation of the microrelief, micropolarity, and intra- and intermolecular mobility of biological objects; and (3) the determination of the distance between chosen parts of systems of interest. The labeling approach makes it possible to work in whole native cellular and subcellular structures in aqueous, diluted solutions. The measurements are fast and widely available.

1 Principles

1.1 Spin Labeling

1.1.1 General

In the overwhelming majority of stable nitroxide radicals (NRs) used as spin labels and probes, the nitroxide group is stabilized by a substituent on the α-carbon atoms; methyl groups, for example (Fig. 1). Spin labels generally include fragments of already known, widely accepted specific reagents for functional groups of proteins, lipids, nucleic acids, and other biological compounds. The nitroxide group with unpaired electron produces simple, well resolved, and comparatively easily treated electron spin resonance (ESR) spectra that are sensitive to the molecular motion of the nitroxide band and its interactions with other paramagnetic materials. In a constant magnetic field of strength H_0, electron spins orient themselves in two directions, that is, along the field and against the field (the Zeeman Effect). Superposition of a perpendicular electromagnetic field of frequency ν in the microwave region results in reorientation of the spins and resonance absorption of the microwave energy occurs. The condition of the resonance is the equality

$$h\nu = g\beta H_0, \qquad (1)$$

where β is the Bohr magneton and g is the g-factor that is characteristic of magnetic momentum of the nitroxide.

The unpaired electron of nitroxide is delocalized over the oxygen and nitrogen. In the spherical symmetrical S state, the delocalized electron undergoes a contact interaction with the spin of the nitrogen nucleus that causes (for ^{14}N) isotropic hyperfine splitting (A_{iso}) into three components corresponding to orientation of the nuclear spin with magnetic quantum number $m = 1$ along ($m = -1$), against ($m = +1$), and perpendicular to ($m = 0$) the constant magnetic field, correspondingly. The A_{iso} is proportional to the electron spin density on the nuclear spin.

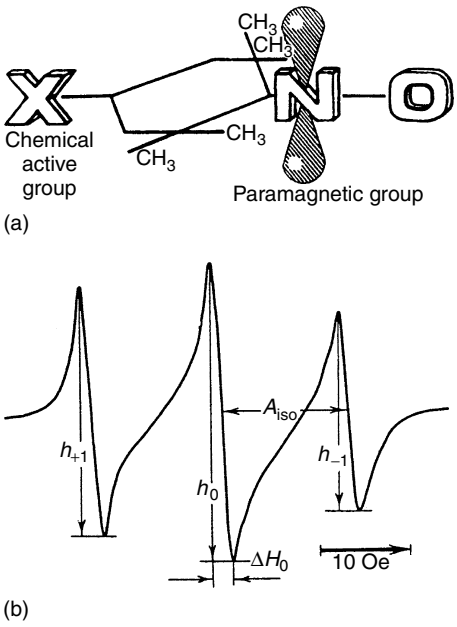

Fig. 1 (a) Schematic presentation for a nitroxide spin label, and (b) schematic spectrum of a nitroxide in solution.

Another type of electron–nuclear spin interaction is associated with localization of the electron on the p-orbital of nitrogen, and therefore, depends on the angle between the direction of the axes of the p-orbital and the constant magnetic field. Such an interaction gives rise to anisotropic hyperfine splitting (A_{aniso}).

1.1.2 Rotational Diffusion of Nitroxide Label

The nitroxides are asymmetric particles (Fig. 1a) characterized by three values of the g-factor (g_x, g_y, g_z) and A_{aniso} (A_x, A_y, A_z). In the immobilized state (frozen or supercooled solutions), the ESR spectra are superpositions of the *microspectra* of an enormous number of radicals with different orientations. The motion of the radicals results in averaging anisotropic effects. According the theory, a value of the time of the nitroxide isotropic rotational diffusion by one radian (correlation time, τ_c) in the region $\tau_c = 1 \times 10^{-10} \div 2 \times 10^{-9}$ s can be calculated from ESR spectra by using the formula,

$$\tau_c = \frac{2.7 \times 10^{-10}}{\left\{\left[\left(\frac{I_0}{I_-}\right)^{1/2} - 1\right]\Delta H_0\right\}} \quad (2)$$

where ΔH_0 is the width of the central component of the spectrum in milliteslas (mT) and I_0 and I_{-1} are the intensities of components with $m = 0$ and $m = -1$ respectively (Fig. 1b). Special methods were developed for the measurement $\tau_c = 10^{-4} \div 10^{-8}$ s.

1.1.3 Nitroxides as Dielectric, pH, Redox, and Imaging Probes

The magnetic parameters of NRs, the g-factor, and the hyperfine splittings A_{iso} and A_{aniso} are sensitive to the properties of the medium (e.g. micropolarity and ability to form hydrogen bonds with the $N-\dot{O}$ group). The physical reason for such dependence is that the contribution of the resonance structure on the right

$$N-\dot{O} \longleftrightarrow \dot{N}^{+} - O^{-}$$

causes an increase in the spin density of unpaired electrons on the nitrogen atom and therefore increases the A_{iso} and A_{aniso} values. For example, $A_{iso} = 1.4 + 0.064\ (\varepsilon_0 - 1)/(\varepsilon_0 + 1)$, where ε_0 is the dielectric constant and A_{iso} is given in millitesla. Protonation of the $N-\dot{O}$ group leads to the value of $\Delta A_{iso} = 0.57$ mT. At protonation of other groups of the nitroxide rings, the value ΔA_{iso} can reach 0.35 mT. The g-factor is also reported to be sensitive to the medium.

NRs are relatively stable toward oxidation, but they can be readily reduced to the

corresponding hydroxylamines. The redox potential of a nitroxide (0.2–0.3 eV) is high enough to oxidize such biological compounds as ascorbic acids, semiquinones, superoxide radical, and Fe^{+2}. Therefore, NRs can serve as redox probes.

1.1.4 Double-labeling Technique. Spin Label–Spin Probe Method: Spin-oxymetry

Under certain circumstances, the ESR spectra of paramagnetic centers will respond suitably to the approach of other centers. Two types of spin–spin interactions are distinguished: (1) dipole–dipole interaction associated with induction by the magnetic dipole of one paramagnetic group of a local magnetic field at the site of another paramagnetic center; and (2) exchange interaction caused by an overlap of the orbitals of unpaired electrons.

For a pair of dipoles, the value of magnetic interaction is

$$\Delta H_{\mathrm{dd}} = \frac{\mu_1\mu_2}{r^3} - \frac{(\mu_1 r)(\mu_2 r)}{r^5} \qquad (3)$$

where μ_1 and μ_2 are magnetic moments and r is the distance between the spins.

The degree of overlap of orbitals with unpaired electrons is quantitatively characterized by the value of the exchange integral I. The value of I is about 10^{13} s^{-1} at the van der Waals distance and decreases exponentially with increasing distance between the spins. The exchange interaction usually prevails over the dipole–dipole interaction at $r < 0.8$–1.0 nm and therefore is suitable for the study of closely disposed paramagnetic materials.

Dipole–dipole interaction is applicable to systems with remote centers. For example, the distance between the pairs of nitroxide spin labels up to 3.0 to 3.5 nm can be calculated by formula:

$$r = 1.6(\Delta H_{\mathrm{dd}})^{-1/3}, \qquad (4)$$

where ΔH_{dd} (mT) is the broadening of the ESR line.

Recently, many modifications of pulse ESR have been designed that allowed the improvement of the distance-measurement accuracy and to expand range of distance available for ESR spectroscopy. The principal advantage of such pulse methods is the direct determination of spin-relaxation parameters that, in turn, are directly related to spin–spin interactions, depending on distances.

The investigation of the paramagnetic contribution of ions to the value of the spin–lattice relaxation rate spin label has resulted in the extension of the distance that can be measured up to 6 nm. When a nitroxide spin label encounters a spin probe, that is, a chemically inert paramagnetic species (e.g. ferricyanide or diphenylchromium) that diffuses freely in solution, the magnitude of broadening of the label ESR line ΔH (mT) is related to the rate constant of the exchange interaction k_{ex} ($M^{-1}s^{-1}$) by the following equation:

$$\Delta H = 6.52 \times 10^{-9} k_{\mathrm{ex}} C \qquad (5)$$

where C is the molar spin probe concentration. Measurement of ESR spectra parameters allows one to determine the value of k_{ex} in the range of 10^6 to 10^{10} M^{-1} s^{-1}. For a particular pair of paramagnetic species, the value of k_{ex} is proportional to the collision frequency, and therefore, depends on chemical structure, microviscosity, steric hindrances, concentration of O_2, and distribution of electrostatic charges in the region of encounters with the use nitroxide probes of different electrostatic charges. Hence, after preliminary empirical calibration, the spin label–spin probe method based on examining k_{ex} can be used for experimental study of these factors in biological objects.

1.1.5 New ESR Techniques

In high-frequency ESR spectroscopy (HF ESR) that generates strong magnetic fields (up to 9 T), the increased magnetic field leads to increasing spectral sensitivity to motion dynamics sensitivity in a slow-motion regime. Recently, significant progress in HF ESR has been achieved with the use of millimeter-wave quasi-optic technique, permitting the construction of a 9-T, 250-GHz (1.2 mm) spectrometer.

The 2D ESR technique relies on selective irradiation of a particular resonance line with a microwave frequency field and observation of the resulting effects in the rest of the spectrum. This method provides a 2D display of the homogeneous linescape across an inhomogeneous ESR spectrum. This approach allows direct study of dynamic processes (rotational and translational diffusion, electron transfer) and static dipole and exchange spin–spin interactions. The possibility of the two-dimensional approach has been significantly extended with the use Fourier transform electron spin resonance (2D FT ESR) and electron spin–echo techniques. Multiple quantum ESR recently developed for measuring distances between spins (r) longer than 1.2 nm is based upon double-quantum coherence pulsed ESR methods. Introducing an extensive cycling of a four-pulse sequence allows the determination of dipole–dipole splitting in the homogeneous ESR spectrum. The latter is directly connected to the r value. The electron nuclear double resonance (ENDOR) method provides direct structural information about a paramagnetic molecule orientation and conformation. Another method that is important for structure assignment is the electron–nuclear–nuclear triple resonance spectroscopy, which is an extension of the ENDOR method.

Among applications of new ESR techniques based on continuous wave illumination (CW ESR), the following ones can be pointed out: (1) site-directed spin labeling; (2) rigid incorporation of a spin label in proteins backbone alpha chain; (3) using fast Fourier transform deconvolution; (4) ENDOR of labeled enzyme-active centers; (5) pairwise interaction spin–spin interaction on a solely tumbling macromolecule; (6) and measurements of depth of immersion and location of paramagnetic centers.

1.2 Luminescent Labeling

1.2.1 General

The main parameters of both fluorescence and phosphorescence are their intensity I, the line shape and frequency of the maxima of spectra ν_{max}, the quantum yield ϕ, and the lifetime of the excited state τ^*. A significant difference between fluorescence and phosphorescence is that the lifetimes of the excited state during fluorescence ($\tau^*_f = 10^{-8} - 10^{-10}$ s) are much shorter than phosphorescence lifetimes ($\tau^*_{ph} = 10^{-3} - 10^{2}$ s). Another distinguishing feature of a phosphorescent molecule is the formation of the triplet, a paramagnetic state after excitation, and such a chromophore may serve as a triplet label.

1.2.2 Rotational Diffusion of Luminescent Labels

Chromophores that are being used as luminescent labels usually have asymmetric adsorption and emission transition moments and are sensitive to the polarization of incident light. If the rotation time τ_R of the chromophore is comparable to or shorter than its excited lifetime τ^*, the emitted light will be depolarized (Fig. 2). A characteristic parameter of depolarization

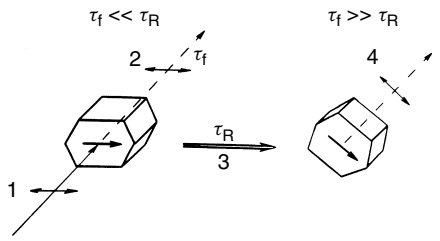

Fig. 2 Schematic representation of the dependence of fluorescent depolarization of a chromophore on the rotational correlation time τ_R and the excited state lifetime τ_f: 1, irradiation by polarized incident light; 2, polarized fluorescence from *immobile* chromophore; 3, rotation of the chromophore; 4, depolarized fluorescence from mobile chromophore.

is the anisotropy,

$$r = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}}, \qquad (6)$$

where $I_{\parallel}$ and $I_{\perp}$ are the intensities of emitted light passing through the polarizer with the electric axis directed parallel or perpendicular, respectively, to the polarization of the incident light. For a spherical molecule,

$$\frac{r_0}{r} = 1 + \frac{\tau^*}{\tau_R} = 1 + \frac{3k_B T\tau^*}{4\pi b^3 \eta} \qquad (7)$$

where r_0 is the anisotropy for a chromophore without rotation, β is the radius of rotation, and η is the viscosity of the medium. Measurement of the dependence of r/r_0 on T/η allows determination of the value of τ_R if τ^* is known. The value of τ_R can be measured directly from the change in the anisotropy after pulse radiation of the sample under study. The aforementioned technique is concerned with rotational diffusion of protein molecules in solution or lipids in membranes with $\tau_R = 10^{-8} - 10^{-9}$ s (fluorescence) and macromolecules in membranes $\tau_R = 10^{-5} - 10^{-6}$ s (phosphorescence).

1.2.3 Molecular Dynamics and Micropolarity of the Media

The excitation of a chromophore is accompanied by a change in the electric dipole moment of the molecule. This involves a change in the energy of interaction with the surrounding dipole molecules. If the characteristic dipole rotational correlation time τ_R in the medium is much longer than the lifetime of the fluorescence or phosphorescence τ^*, the dipoles have no chance to follow the change in the light-induced electric field, and the transition from the *unsolvated* excited state to the ground state takes place. In another limiting case, where $\tau_R \ll t^*$, the interaction between the dipoles and excited molecule lowers the energy of the system, and emission is effected from the *solvated* level. The relaxation can be followed by time-resolved spectroscopy, measuring the kinetic value of the shift of the maximum of the fluorescent or phosphorescent spectra $\nu_{max}(t)$ (relaxation shift):

$$\nu_{max}(t) - \nu_{max}(\infty) = [\nu_{max}(0) - \nu_{max}(\infty)] \times \exp\left(-\frac{t}{\tau_r}\right), \qquad (8)$$

where the indexes t, ∞, and 0 are related to the ν_{max} of the time-resolved emission spectrum at a given moment t, $t \to \infty$ and $t = 0$. The value of τ_R can be also estimated by measuring the temperature dependence of the ν_{max} of steady state emission spectra. The value of the relaxation shift depends on the electrostatic dipole moment of

the excited chromophore and on the parameters of polarity (in the simplest case, dielectric constant) of the medium. Hence, the latter can be estimated for biological objects (e.g. active centers of enzymes, membranes) after preliminary calibration, using model systems with known properties.

1.2.4 Resonance Energy Transfer Between Chromophores; Quenching of Fluorescence; Fluorescent Recovery after Photobleaching (FRAP)

The electrostatic dipole–dipole interaction between chromophores permits the nonradiative transfer of energy from an excited singlet state of a molecule (a donor, D) to an unexcited singlet state of another molecule (an acceptor, A) via an inductive resonance mechanism. According the theory developed by Förster, the efficiency of the transfer:

$$E_T = 1 - \frac{\phi}{\phi_0} = \frac{R_0^6}{R_0^6 + R^6} \qquad (9)$$

where ϕ and ϕ_0 are the quantum yields of the donor fluorescence with and without the acceptor; R is the distance between D and A, and R_0 is the critical distance at which the probability of energy transfer is equal to that of donor excited state deactivation:

$$R_0 = \frac{162K^2}{\pi^5 n^4} \int_0^\infty \frac{f_D(\nu)\varepsilon_A(\nu)\,\mathrm{d}\nu}{\nu^4}, \qquad (10)$$

where the n is refractive index of the medium, $\int$ is the spectrum overlap of the donor fluorescence $f_{D(u)}$ and the acceptor adsorption $\varepsilon_{A(\upsilon)}$, and K^2 is the orientation factor of the dipole pair. For random reorientation of the donor and acceptor transition moments, $K^2 = 2/3$. Measurement of E makes it possible to estimate distances between the centers by 1.0 to 8.0 nm. Lanthanide (chelates of terbium or europium) based fluorescence resonance energy transfer (FRET) is a recent modification of the technique with a number of technical advantages, yet relies on the same fundamental mechanism. The advantages are (1) the value of the critical radius is 5.0 to 7.0 nm; (2) since the donor's emission is unpolarized, the efficiency of energy transfer depends primarily on the distance between donor and acceptor, and not on their relative orientation.

The phenomenon of quenching excited singlet states has been used in the investigation of collisions between fluorescent labels and quenching molecules. The process can be described by the Stern–Volmer equation:

$$\phi_0\phi = 1 + K_\mathrm{q}[Q] = 1 + \tau^* k_q[Q], \qquad (11)$$

where K_q is the Stern–Volmer constant and k_q is the quenching rate constant. The range of the k_q values available for the fluorescence quenching technique is 10^8 to 10^9 $\mathrm{M^{-1}s^{-1}}$. Molecules with polar groups and heavy atoms, many aromatic molecules, and electron acceptors are efficient quenchers, with $k_\mathrm{q} = (3\text{–}6) \times 10^9$ $\mathrm{M^{-1}s^{-1}}$.

The relatively slow diffusion of fluorescent probes and labeled macromolecules is studied by Fluorescent Recovery after Photobleaching (FRAP) techniques, which are based on photobleaching of small portions of the objects under study by a laser pulse, followed by monitoring of fluorescence recovery as a result of diffusion from an adjacent portion of the system.

1.2.5 Triplet, Photochrome, Triplet–photochrome, and Spin-triplet-photochrome Labeling

The excited triplet state has two unpaired electrons and can be considered a specific biradical, triplet label. Therefore, the processes of deactivation of the triplet

state can be accelerated owing to exchange spin–spin interaction with other paramagnetic molecule by means of triplet–triplet (T–T) energy transfer or intercrossing. In particular, the experimental values of k_{TT}, the rate constant of the triplet state deactivation, can be written as follows:

$$k_{TT} = 10^{15} \exp(-26R), \qquad (12)$$

where R (nm) is the distance between the triplet label and a quenching molecule separated by *nonconducting* media (e.g. molecules or groups with saturated chemical bonds) and the result is given in reciprocal seconds. Dynamic exchange interactions upon collisions between exchanging centers in solution are very effective. The long lifetime of a triplet label in the excited state (τ^*_{ph} is in the range 10^{-1}–10^{-6} s) offers possibilities for measuring the rates of such slow dynamic processes as collisions of proteins in solution and diffusion of small molecules in rigid membranes. Nitroxide spin probes, complexes of paramagnetic metals, biological molecules (say, quinones, vitamins, etc.), and O_2 have proved to be effective quenchers of triplet labels.

The phenomenon of photochromism involves light-induced reversible transitions of a chromophore (A) to another form (B); for example, the photoisomerization a fluorescent *trans*-stilbene derivative to the non-fluorescent *cis*-stilbene. The latter includes the rotation of phenyl groups as a necessary step in the transformation. In a viscous medium and in systems with strong steric hindrance, the rotation can be the rate-determining stage; therefore, the experimental rate constant of the photoisomerization k_{is} of the photochromic label can be a characteristic of the microviscosity of an object of interest.

Photochrome labeling allows one to investigate relaxation processes in biological systems using sensitive and widely available fluorescence techniques. An approach was developed to determine the rate constant of very rare collisions, including those between macromolecules in rigid media such as biological membranes. The photochrome–triplet labeling approach is based on monitoring the rate at which the photochromic stilbene label *cis–trans* isomerization is sensitized by the triplet–triplet energy transfer between this label and a triplet label (say, Erythrosine). The relatively long lifetime of the excited triplet state of the triplet label and nonreversible character of the photoisomerization make it possible to *integrate* information on the energy transfer by accumulating the photoreaction product, a *trans*-stilbene derivative. The characteristic time of the photochrome–triplet labeling method is about 1 s. These unique characteristics of the approach allow one to determine the rate constant of very rare collisions, including those between macromolecules in such rigid media as proteins in biological membranes. An additional step in the cascade reaction scheme is the quenching of the sensitizer triplet state with relatively low-concentration radicals (Fig. 3). This technique combines the three types of biophysical probes: stilbene photochrome probe, triplet probe, and stable nitroxide-radical spin probe, which depresses the sensitizer exited triplet state.

1.2.6 Dual Fluorophore-spin Labeling: High-sensitivity Redox Probes, Spin and Nitric Oxide Traps

The quantitative characterization of quenching and redox processes is based upon the use of two molecular subfunctionalities (a fluorescent chromophore and a stable nitroxide radical) tethered together

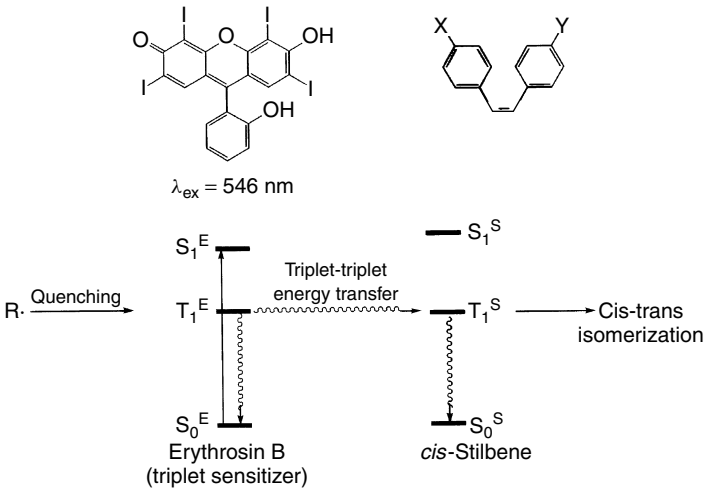

Fig. 3 Representation of the energy levels of the cascade reactants and a competition between the $T_1^E \rightarrow T_1^S$ and $T_1^E \rightarrow S_0^S$ processes.

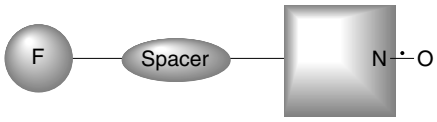

Fig. 4 Schematic representation of dual fluorophore–nitroxide molecule.

by a spacer. A typical double probe consists of fluorophore and nitroxide fragments connected by functional groups (a spacer) (Fig. 4). In the dual molecule, the nitroxide is a strong intramolecular quencher of the fluorescence from the chromophore fragment. Chemical or photoreduction of this fragment to a hydroxylamine derivative, oxidation of the nitroxide fragment, or addition of an active radical yields the fluorescence increase and the parallel decay of the fragment ESR signal. A reducing substrate (e.g. antioxidant analyte, semiquinone and superoxide radicals, nitric oxide in the nanomolar concentration scale) reduces the nitroxide function resulting in a decay of the nitroxide ESR signal plus concomitant enhancement of the chromophore fluorescence. Organic synthetic chemistry allows playing with the chemical structure of dual molecules of different fluorescence, ESR, and redox properties with a variety of bridges (spacers) tethering the fluorophore and nitroxide fragments. It was demonstrated that variation of the chemical structure of nitroxide moieties allows measuring of the concentration of nitric oxide, superoxide, and antioxidants (ascorbic and uric acids, flavons) in biological liquids (human blood plasma, fruits juices), that is to say, establishing the reducing status of these objects.

1.2.7 New Fluorescence Technique

In confocal microscopy, a tiny open volume element of about 0.2 fL is created by a focused laser beam. When a fluorescent molecule enters the confocal volume, it becomes excited. In this technique, the space distribution of a fluorescent fluorophore and the fluctuation of fluorescence intensity

are analyzed. Recent developments in fluorescence spectroscopy and microscopy have made it possible to detect and image single molecules. These techniques allow the conducting of spectroscopic measurements for studying chemical and biological species and their interaction with the environment. Single molecular measurement offers time resolution to monitor dynamic processes such as translation, orientation, and enzymatic reactions on a timescale from milliseconds to ten seconds. Fluorescent quantum efficiencies greater than 0.1 can be studied with this technique. The techniques that have evolved to the level of single molecule sensitivity at room temperature are flow cytometry, confocal fluorescence correlation spectroscopy, and microdroplet technique.

Two-photon molecular excitation is performed by very high local intensity provided by tight focusing in a laser-scanning microscopy. This technique is combined with the temporal concentration of femtosecond pulsed lasers that produce a stream of pulses with a pulse duration of about 100 fs at a repetition rate of about 80 MHz. Advantages of the two-photon laser spectroscopy are as follows: high resolution, tolerance of infrared light by biological objects, different selection rule, and vibronic coupling. In home dual-color cross-correlation fluorescence spectroscopy experiments, a sample containing two fluorophores, with different emissions in each molecule, is irradiated with two lasers (or with one laser) to perform simultaneous excitation of the fluorophores. This technique in combination with confocal laser microscopy allows the separation of a microscopic volume with two different fluorophores from a volume with only one fluorophore, and therefore, the monitoring of dissociation of the dual-labeled molecules or association of two single-labeled molecules.

With the development of the near-infrared (NIR) laser diodes, the synthesis of fluorescent dyes with excitation and emission in the NIR wavelength regime has accelerated in the past decade for microscopy application. Fluorescence lifetime imaging is one of the techniques that attract much attention. Fluorescence lifetimes possess the benefit of being independent of local intensity, concentration and photobleaching of the fluorophore, and scattering in complex structure. This

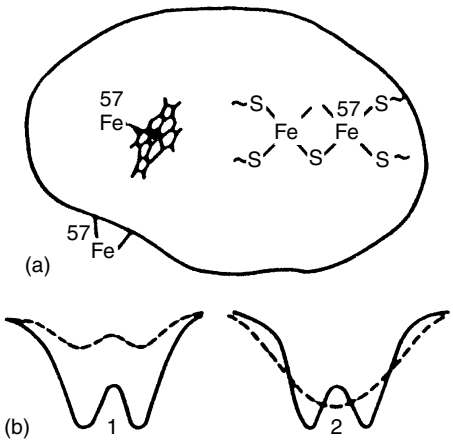

Fig. 5 The Mössbauer labeling methods. (a) Possible methods of introducing labels (^{57}Fe) into proteins. (b) Expected changes in Mössbauer spectral parameters for labels mobilities with $\tau_c = 10^{-7}$ s and amplitude of 0.01–0.02 nm: solid lines, absence of such a mobility; dashed lines, show presence. Curve 1, vibrational motion (f′decreases; line width does not change); curve 2, diffusional motion (line width increases, f′does not change).

technique in combination with FRET allows the investigation of interactions of proteins and nucleic acids within a cell.

1.3 Miscellaneous Labeling Methods

1.3.1 Mössbauer Labels

The Mössbauer method is based on the phenomenon of nuclear gamma resonance (NGR), for example, the transition of a nucleus (e.g. ^{57}Fe) from the ground state to the excited state upon absorption of a γ-quantum emitted by ^{57}Co. The dependence of the intensity the emitting and absorbing nuclei is indicated in the so-called *Mössbauer spectrum* (Fig. 5). Parameters of the NGR spectra are extremely sensitive to the amplitude x of the Mössbauer atom oscillation and the diffusion coefficient D, and therefore, to the dynamics of an object of interest. For example, for ^{57}Fe:

$$f' = 10^{-2300\langle x\rangle^2} \qquad (13)$$

and when the amplitude increases by 0.05 nm, the f' value decreases by a factor of 10^5. Mössbauer atoms can be introduced into various portions of biological structures, say active centers of Fe-containing enzymes, via chemical reactions, absorption, or biosyntheses. In a complimentary technique of the Rayleigh scattering of Mössbauer radiation, the radiation is incident upon the sample. The sample does not need to be labeled with ^{57}Fe; nevertheless, the analysis of the radiation gives the mean square displacement of the scattering atoms averaging over all the atoms of the sample.

1.3.2 Nuclear Magnetic Resonance Probes

Probes modified specifically with isotopes (^{2}H, ^{13}C, ^{15}N, ^{19}F, ^{17}O, ^{28}Na, etc.) are characterized by distinct and easily interpreted NMR spectra. Such modifications can be exemplified by the introduction of ^{13}C into the C=O group of lysine, ^{15}N into the amide group of glycine, and ^{2}H into specific positions of lipid probes. The most widely used NMR probes that are commonly combined with spin labeling are deuterated probes. Isotopes ^{13}C and ^{15}N are the most suitable for studying the molecular dynamics of biological molecules.

1.3.3 Electron and X-ray Scattering Labels

The relative intensity of electron scattering and X-ray scattering (I/I_0) increases, other conditions being equal, with atomic number (Z) of the component atom: $I/I_0 \sim Z^2$. A number of polynuclear complexes and clusters of heavy metals are used nowadays as electron-scattering labels: colloid particles and clusters of gold, polymercury mercarbides, and compounds of palladium and iodine. Analysis of electron micrographs and X-ray scattering of the labeled biological objects allows one to investigate the location of specifically labeled portions.

2 Applications

2.1 Enzymes and Proteins

2.1.1 Active Sites of Enzymes

Monitoring the mobility of spin and luminescence labels and measuring the magnetic and electrostatic interactions between them can be used to study many phenomena, including the chemical nature and mutual disposition of modified catalytic and binding chemical groups, the size and form of a cleft of enzyme-active

centers, the distribution of electrostatic charges around the centers, the location of specific zones on an enzyme complex, and the rotation of protein globules.

Serine proteases are used as a *proving ground* for various versions of the spin-labeling method. The principal catalytic groups of the α-chymotrypsin active center, namely, Ser195, His57, and Met192, were modified by nitroxide spin labels. The ESR spectra of spin-labeled preparations were highly sensitive to fine changes in the structure of the active centers at the interactions with the substrate analogs. When nitroxide derivatives of sulfamides having bridges of varying lengths between the aromatic groups and nitroxide fragment were included in the enzyme-active center, the mobility of such a fragment could be drastically enhanced by using a probe longer than 1.45 nm. Physical labeling methods were applied to determine the mutual arrangement of Fe_nS_n clusters, the ATP center of nitrogenase and the location of these centers on the enzyme macromolecules, and for estimation of distances between the nucleotide-binding centers of H^+ ATP synthase (4.0–5.0 nm).

The labeling method was used to probe the molecular nature of the binding pocket of a G protein–coupled receptor and the events immediately following the binding and activation. The substance P peptide, a potent agonist for the neurokinin-1 receptor, has been modified with a nitroxide spin probe specifically attached at Lys-3. The EPR spectrum of the bound peptide indicates that the Lys-3 portion of the agonist is highly flexible. A slight increase in the mobility of the bound peptide in the presence of a non-hydrolyzable analog of GTP was detected, indicative of the alternate conformational states described for this class of receptor. *S*-adenosylmethionine (AdoMet) synthetase (I) of *Escherichia coli* is one of numerous enzymes that have a flexible polypeptide loop that moves from gate access to the active site in a motion that is closely coupled to catalysis. Site-directed spin labeling was used to introduce nitroxide groups at 2 positions in the loop to illuminate how the motion of the loop is affected by substrate binding. The results suggest that the motion of the loop may be an intrinsic property of the protein and not be strictly ligand-modulated.

The confocal fluorescence coincidence analysis has been employed for a rapid homogeneous assay for restriction endonuclease *Eco*RI. This methodology has been improved by the application of two-photon excited, dual-color, cross-correlation spectroscopy on the level of single diffusing molecules. A double-strand of DNA was labeled with Rhodamin green and Texas red. The kinetics of the enzymatic cleavage of the labeled DNA by restriction endonuclease was monitored by this new technique. The single-molecule fluorescence technique was used for the study of differences in the chemical reactivity of individual molecules of enzymes. Enzyme molecules are presented at very low concentration (7.6×10^{-17} to 1.5×10^{-16} M) in a narrow capillary and each discrete molecule produces a discrete zone. The kinetics of synthesis of a fluorescent product, 2′-(2-benzothiazol)-6′-hydrobenzthiazol, produced by single alkaline phosphatase molecule has been investigated.

Rhodanase was labeled at its catalytic site with the phosphorescence probe eosin isothiocyanide. The accessibility of molecules to the probe was determined by phosphorescence lifetime-quenching studies. The use of a novel pulsed ESR technique for distance measurement based on the detection of double-quantum

coherence (DQC), which yields high quality dipolar spectra, significantly extended the range of measurable distances in proteins using nitroxide spin-labels. Eight T4 lysozyme (T4L) mutants, doubly labeled with methanethiosulfonate spin-label (MTSSL), have been studied using DQC-ESR at 9 and 17 GHz. The distances span the range from 2.0 to 4.7 nm.

The physical basis of an approach rests upon the effect of the local electrostatic potential upon dynamic interactions at encounters with charged quenching molecules resulting in fluorescence (phosphorescence), or between a stable radical, for example, nitroxide, and another charged paramagnetic species. In such cases, the relaxation parameters, that is, the lifetime of the fluorescence (phosphorescence) chromophore or spin–spin and spin–lattice relaxation rates of paramagnetic species are dependent upon the frequency of encounters, and therefore, on local electrostatic fields. Electron-carrier horse heat cytochrome c and dioxygen-carrier sperm-whale myoglobin served as models for determining local electrostatic charges in the vicinity of paramagnetic active sites of metalloenzymes and metalloproteins. Calculations of local charge Z_x in the vicinity of a paramagnetic particle (such as the active site of a metalloprotein or a spin label) colliding with a nitroxide or metallocomplex with known charge Z_p can be carried out with the use of the Debye equation.

Nitroxide spin molecules are convenient probes for the ENDOR application for solving some problems of enzyme catalysis. From ENDOR studies of molecular structures and conformations, several spin-labeled amino acid derivatives incorporated into enzyme-active sites have been reported. For instance, the spin-labeled transition-state analog in the α-chymotripsin reaction, *N*-(2,2,5,5-tetramethyl-1-oxypyrrolinyl)-L-phenylalaninal, has been synthesized. The conformation of the acyl- moiety of the substrate analog in the active site of the reaction intermediate differs significantly from that of the free substrate in solution.

2.1.2 Conformational Changes and Molecular Dynamics

Labeling methods were applied for detecting conformational changes, including large-scale denaturation transitions, predenaturing phenomena, allosteric effects (transmitted from one enzyme subunit to another), conformational changes in enzyme structures other than quaternary (transglobular allosteric transition), and changes in the state of various segments of the active centers of enzymes due to the action of specific reagents on the adjacent segments.

Allosteric effects were first reported by McConnell and associates in studies of horse hemoglobin with the β-SH group modified by a spin label 1.3 to 1.4 nm from the heme active center. Transglobular transitions were studied in a number of proteins, including lysozyme, myoglobin, aspartate aminotransferase, and myosin.

Biophysical labeling methods provide a unique possibility for monitoring local intermolecular dynamics properties in a wide range of correlation times (τ_c is in the range 10^2 to 10^{-10} s). They enable the investigation of the dynamics of different parts of protein globules in the vicinity of the spin, fluorescence, phosphorescence, and Mössbauer labels under various conditions (temperatures 30–330 K, water content, viscosity, substrates, inhibitor additions, etc.). The experiments revealed the following tendency: appropriate physical methods detect the mobility of labels starting from the temperature of liquid

nitrogen; the lower the value of the characteristic frequency of the method, the lower the temperature at which the label mobility can be recorded. Thus, the mobility recorded results from a gradual softening of the protein–water matrix rather than from an individual phase transition.

At physiological ambient conditions, all labeling methods indicate the mobility of labels and surrounding media in the nanosecond temporal regions. A correlation between the temperature dependencies of nonharmonic parameters of Mössbauer atoms in heme, the heme spectra Soret band Gaussian broadening, non-elastic neutron scattering, and the molecular dynamics simulation in myoglobin was demonstrated. According to these data, the anharmonic intramolecular mobility of proteins increases dramatically at $T > 200$ K. This conclusion was confirmed by low-temperature experiments with the use of the fluorescence dynamic Stokes shift, neutron scattering, and molecular dynamics simulation in other proteins, superoxide dismutase, lysozyme, elastase, bacteriorhodopsin, and RNAse. It is necessary to stress that the anharmonic nanosecond dynamics of the proteins recorded with labeling methods only appear if the water content of the sample being studied exceeds a critical value by about 10 to 25%. According to experimental data on Mössbauer spectroscopy, at ambient temperatures, the myoglobin heme group exhibits the unharmonic nanosecond motion with $\langle \Delta x \rangle_{nh} > 0.02$ nm. The flexibility of the cavity of the myoglobin active site is evidenced by the mobility of a spin probe, a derivative of isocyanate attached to the heme group in the single crystal.

The mobility of a single deuterated tryptophane located in a loop of the active site of triosephosphate isomerase has been investigated by solid-state deuterium NMR and solution state 19F NMR. The rate of the loop's opening and closing was detected using samples of the enzyme in the presence and in the absence of a substrate analog DL-glycerol 3-phosphate at temperatures ranging from -15 to $+45\,^{\circ}$C. It was shown that the rate of the loop's opening and closing is of order $10^4\ s^{-1}$. Hinge-bending and substrate-induced conformational transitions in T4 lysozyme in solution were confirmed in a study by site-directed labeling. Both single and pairs of nitroxide spin labels were introduced into different domains of the protein followed by monitoring distances between the labels by ESR technique. In the absence of a substrate, the results are consistent with a hinge-bending motion, which opens the active site cleft. When substrate binding takes place, the relative domain movement occurs.

Simulation studies of typical intramolecular energy transfer experiments reveal that both static and dynamic conformational distribution information can thus be obtained at a single temperature and viscosity. This method was used for the investigation of the refolding transition of *E. coli* adenylate kinase (AK) by monitoring the refolding kinetics of a selected 20-residue helical segment in the CORE domain of the protein.

The local and global dynamics of the *Sulfolobus solfataricus* β-glycosidase were studied by ESR and time-resolved fluorescence techniques. For EPR investigations, the protein was covalently modified by the maleimido nitroxide spin label, which is specific for cysteine -SH groups, at position 344 and at position 101, where Ser101 was changed into a cysteine by site-directed mutagenesis. The labeled proteins underwent temperature perturbation in the range 290 to 335 K. The general dynamic

information was deduced from the analysis of the fluorescence emission decay of the tryptophanyl residues that are present in each region of the protein structure.

2.2 Membranes

Specific modification of individual lipid and protein parts of biological and model membranes by whole sets of labels and probes allows the biophysical labeling method to be extremely effective in investigating membrane dynamics and microstructure. Monitoring of the rotational diffusion of nitroxide, fluorescent, and phosphorescent derivatives of lipids and proteins, and their collisions, enables one to determine thickness, the microviscosity profile of membranes, membrane heterogeneity, and phase transitions, as well as to discover phenomena related to the lateral diffusion of lipid and protein associations in membranes. Spin and fluorescence labeling approaches have indicated significant similarities between the structural and dynamic properties of model bilayer liposomes and the lipid phase of such biological membranes such as erythrocytes, the sarcoplasic reticulum, and microsomes. A number of specific problems associated with the intrinsic inhomogeneity of cells, biochemical and biophysical processes (including redox ones), and cell organization can be readily solved by means of labeling approaches. In differentiated cells (ovarian cells, spermatozoa), the FRAP method indicated the presence of protein domains and of different microcompartments in various parts of the cells that differed with respect to diffusion coefficients and mobile fractions. The values of intercellular pH monitored by a fluorescent probe (fluorescein after enzymatic deacetylation) were found to differ in various compartments of the cells.

The distribution of LW peptide between coexisting ordered and disordered lipid domains was probed by measuring the LW Trp fluorescence quenched by a nitroxide-labeled phospholipid that is concentrated in disordered lipid domains. Strong quenching of the Trp fluorescence (relative to quenching in model membranes lacking domains) showed that LW peptide was concentrated in quencher-rich disordered domains and was largely excluded from ordered domains. Nitroxide spin label studies with high-field/high-frequency ESR and two-dimensional Fourier transform ESR enable one to accurately detect distances in biomolecules, unravel the details of the complex dynamics in proteins, characterize the dynamic structure of membrane domains, and discriminate between bulk lipids and boundary lipids that coat transmembrane peptides or proteins.

The EPR spectroscopic characterization of a recently developed magnetically oriented spin-labeled model membrane system was reported. The oriented membrane system is composed of a mixture of a bilayer-forming phospholipid and a short-chain phospholipid that breaks up the extended bilayers into bilayered micelles or bicelles that are highly hydrated (approx. 75% aq.). Paramagnetic lanthanide ions (Tm^{3+}) were added to align the bicelles such that the bilayer normal is collinear with the direction of the static magnetic field. The nitroxide spin probe 3β-doxyl-5α-cholestane (cholestane) was used to demonstrate the effects of macroscopic bilayer alignment through the measurement of orientational dependent hyperfine splittings that were close to A_{yy}. The EPR signals of cholestane inserted into oriented and randomly dispersed DMPC-rich

bilayers have been investigated over the temperature range of 298 to 348 K.

2D-ELDOR spectroscopy has been employed to study the dynamic structure of the liquid-ordered (L_o) phase versus that of the liquid-crystal (L_c) phase in multibilayer phospholipid vesicles without (L_c) and with (L_o) cholesterol, using end-chain and headgroup labels and spin-labeled cholestane. Fluorescence correlation spectroscopy was used for investigation of the size and the size distribution of liposomes loaded with a fluorescence probe.

2.3 Nucleic Acids

The following methods have been developed for modification of nucleic acids: (1) covalent attachment of spin and fluorescent labels to functional groups of the nucleotide bases; (2) covalent attachment of labels to hydroxyl groups on the ribose glucosyl rings; (3) alkylation or acylation of the SH group of the 4-thiouracil or the NH_2 group on the aminoacyl residue of tRNA; (4) enzymatic synthesis of nucleic acids with the use of a labeled base; and (5) intercalation of spin and fluorescent probes between bases in the double-helix portion of nucleic acids, and complexation with paramagnetic (Mn^{+2}) or Mössbauer (^{57}Fe) atoms. The extent of the immobilization of the labels and probes and the spin–spin interactions between them are determined by the structure of the nucleic acid, the length and flexibility of the label, and ambient conditions (pH, temperature, ionic strength, destructive forces, and degrees of binding of various compounds). The thermal- and pH-induced transitions of nucleic acids at their melting temperatures are accompanied by a drastic increase in the mobility of the attached spin labels. The ESR spectra of spin-labeled preparations of nucleic acids are sensitive to fine conformational changes as well.

The dynamics of iron nuclei in the condensates obtained by interaction of Fe^{III} with DNA, (DNA monomer), has been investigated by ^{57}Fe Mössbauer spectroscopy. Functions of the parameters isomer shift and nuclear quadrupole splitting in temperature ranges 20 to 260 K were employed to investigate the dynamics of Fe nuclei and showed linear trends in the temperature ranges 20 to 150 and 150 to 260 K, respectively, the latter with larger slopes. Site-directed spin labeling utilizes site-specific attachment of a stable nitroxide radical to probe the structure and dynamics of nucleic acids. 4-thiouridine base was introduced at each of six different positions in a 23-nucleotide RNA molecule. The 4-thiouridine derivatives were subsequently modified with one of three methanethiosulfonate nitroxide reagents to introduce a spin label at specific sites. The motion is similar to that found for a structurally related probe on helical sites in proteins, suggesting a similar mode of motion. The nitroxide spin-labels are covalently linked to a deoxyuridine residue using either a monoacetylene or diacetylene tether. A detailed analysis of the EPR spectrum of duplex DNA in solution, spin-labeled using the diacetylene tether, demonstrates that the motion of the nitroxide can be modeled in terms of this independent uniaxial rotation together with motion of the DNA, which is consistent with the global tumbling of the duplex.

New genome sequence information is rapidly increasing the number of nucleic acid (NA) targets of use for characterizing and treating diseases. Detection of these targets by fluorescence-based assays is often limited by fluorescence background from unincorporated or unbound probes

that are present in large excess over the target. To solve this problem, energy transfer–based probes have been developed and used to reduce the fluorescence from unbound probes. The quenching approach of a two-color NA assay with a correlated, two-color, single-molecule fluorescence detection was employed. A method for generating fluorescent probes from RNA or DNA samples was described. In this method, an amine-modified base was added to the ends of the primers so that a dye could be introduced into each DNA and onto the end of each product. This allows labeling of a very small amount of total RNA in such a way that reproducible experiments were performed. It was shown that FRET between fluorescein labeled to poly(C) and an intercalator agent takes place when single-stranded poly(C) hybridizes with poly(I).

The following application of the labeling approach can be also pointed out: (1) protein-induced DNA blending studied by labeling a 30-base pair strand of DNA, one with europium donor chelate and the other with the acceptor dye Cy5; (2) detection of the association between actin and the protein dystropin inside a muscle cell; (3) time-resolved identification of individual label mononucleotides in water; (4) DNA sequences on the single molecule level; (5) detection of individual tumor marker molecules in neat human.

2.4 Cells and Organs

Fluorescence lifetime imaging microscopy using multiphoton excitation techniques is now finding an important place in the imaging of protein–protein interactions and intracellular physiology. An example of a typical application of the system was provided in which the fluorescence resonance energy transfer between a donor–acceptor pair of fluorescent proteins within a cellular specimen is measured. The recent development of automated fluorescence imaging systems has enabled fluorescence microscopy to be used for the purposes of compounds screening. This technique has found various applications, including screening for the effect of kinase inhibitors on the cytoskeleton, agonist-stimulated receptor internalization, and protein phosphorylation and acetylation.

L-band (low-frequency) EPR imaging instrumentation has been developed in order to elucidate spatially defined differences in tissue metabolism and the redox status. For example, 3D images of nitroxyl compounds in a rat tail and isolated rat heart have been reported, which reflect the local metabolic and oxygenation status. Very recently, a new magnetic resonance imaging method (MRI) was presented that can ''visualize'' free radical generation in animals by means of MRI. The advantages of MRI, the combination of MRI and EPR, and PEDRI (proton electron double resonance imaging), and recent progress of these methods were demonstrated.

The kinetics of reductions of the radical R*, 5-dimethylaminonaphthalene-1-sulfonyl-4-amino-2,2,6,6-tetramethyl-1-piperidine-oxyl, by blood and its components were studied using the EPR technique. The results demonstrate that: (1) the erythrocytes catalyze the redaction of R* by ascorbate; (2) the rate of redaction of the radical is high though it does not penetrate the cells; and (3) in human erythrocytes, there is an efficient electron transfer route through the cell membrane. The study points out that R* is a suitable spin label for

measuring the reduction kinetics and antioxidant capacity in blood as expressed by reduction by ascorbate. The nitroxides are reduced to corresponding hydroxylamine in cellular incubations as well as *in vivo* incubations. *Tissue hypoxia* is known to significantly enhance the rate of the nitroxide reduction.

Fluorescence *in situ* hybridization (FISH)-based techniques were used in the clinical detection of genetic alterations in tumor cells. Fluorescent DNA probes also enabled screening for very subtle chromosomal changes. A growing number of FISH-based cytogenetic tests are employed in clinical laboratories to support a physician's diagnoses of the causes and the course of a disease. FISH-based analyses have been applied very successfully to the analysis of single cells and have demonstrated the existence of cell clones of different chromosomal make-up within human tumors. An immunofluorescence assay was developed to identify proteins specifically binding to oligonucleoside phosphorodithioate (ODN) aptamers from a bead-bound ODN library. It was shown that high-resolution localization of genes on chromosomes is possible with specially correlated introduction of fluorescent DNA probes (fluorescence *in situ* hybridization). This method allows the mapping of cloned genes to a locus defined by a chromosome band.

2.5 Miscellaneous

2.5.1 Biologically Active Compounds, Biological Analysis, Pharmokinetics

Syntheses and applications have been reported for many types of spin- and fluorescent-labeled analogs of amino acids, steroids, phospho-organic compounds, alkaloids and terpenes, nucleotides and their fragments, coenzymes (vitamins B_{12} and B_6, protohemin, NADH, etc.), and haptens. Advances in the synthetic chemistry of nitroxide analogs of medical preparations such as morphine, local anesthetics, anticancer drugs (analogs of thiophosphoamin, rubromycin, adriamycin, nitroarylaziridnes, nitrosourea, diethyleneimineurethanic acids, and anthracycline drugs) have provided the basis for further development in basic and applied biochemical and pharmacokinetic investigations.

Some of the most promising applications of fluorescence and spin labeling appear to entail the analysis of biologically active compounds, metal ions, biopolymers, and enzymes. Changes in fluorescence, rotational diffusion parameters, dipole–dipole electrostatic and spin–spin interactions under contact between physical probes, and the compound being tested allow one to work out an appropriate analytical procedure in each particular case. A number of procedures featuring fluorescent and spin-labeled chelating reagents have been developed for quantitative assays of Ca^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Co^{2+}, and Na^{+} ions, and for determination of enzymatic activity. The ability of chromophores (propidium, acridine orange, etc.) to change the intensity of fluorescence upon binding with nucleic acids has been widely used in analytical biochemistry. Lanthanide fluorescence chelates have been successfully developed as the fluorescence labels for highly sensitive bioassays. The applications of lanthanide fluorescence labels for time-resolved fluoroimmunoassay (TR-FIA), DNA hybridization assay, cell activity assay, and fluorescence imaging microscopy have been widely investigated.

Nitroxide probes are used as *in vivo* imaging reagent and oximetry probes. The

pharmacokinetics and spatial distribution of the nitroxide in tumor tissue were followed and compared with those in normal tissue. The tumor tissues showed significant heterogeneity in the nitroxide distribution and higher reducing rate compared to the normal tissue.

3 New Trends in Biophysical Labeling

The following main trends in development and application biophysical labeling may be pointed out:

- Synthesis of fluorescent and phosphorescent dyes with excitation and emission in the NIR wavelength regime for microscopy and analysis application.
- Syntheses and application of dual fluorophore–nitroxide probes of different redox potential and fluorophore fragment nature.
- Site-directed incorporation of spin and luminescent label in protein, nuclear acids followed by the investigation with the use modern physical methods.
- Growing employment of recently developed ESR techniques (high-frequency ESR spectroscopy, Fourier transform 2D ESR, ELDOR electron spin-echo techniques, ELDOR and ENDOR, and multiple-quantum ESR) and fluorescence methods such as confocal microscopy, single molecular measurement, multiphoton molecular excitation, fluorescence lifetimes imaging, cascade systems, etc.
- Expanding objects under investigation including cells, organs, and organisms in prospect.
- Wide application in biomedical research and medical diagnostics.

Ligase
An enzyme capable of joining the 5′ and 3′ ends, respectively, of two adjoining nucleic acid molecules, creating a phosphodiester bond.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 7

5′ and 3′
The two ends of a nucleic acid strand are termed the 5′ and the 3′ ends. Enzymatic synthesis proceeds in the 5′ to 3′ direction.

Ligation template
A nucleic acid molecule with a sequence that allows two probe molecules to hybridize adjacent to each other, allowing ligation of the 5′ end of one to the 3′ end of the other to take place.

DNA ligation is a popular mechanism in analyses of gene sequences. The ligation of pairs of DNA probes upon hybridization to a target nucleic acid sequence creates a contiguous DNA sequence that can be used to infer the presence and nature of target molecules. The ligatable DNA strands can also be coupled to other molecules interacting with targets of interest to increase the range of molecules detectable in ligase-based assays.

In ligase-mediated detection of nucleic acid sequences, the requirements for substrate recognition by ligases may be used to distinguish target sequences that differ in even single nucleotide positions. The covalent link that forms between the probe pairs can be used to connect retrievable functions on one probe to detectable groups on the other. Even more usefully, the resulting contiguous DNA strand can be amplified, along with sequence elements that encode the target specificity of the probes. These principles are being applied in a rapidly increasing range of molecular analyses, including high-throughput genotyping, *in situ* detection of nucleic acid sequences, and highly sensitive protein assays.

1 Principles

1.1 Basis of Ligase-mediated Analyses

Specific nucleic acid sequences can be analyzed using hybridization probes that base pair to the target sequence. For enhanced performance, hybridization probes are often used in combination with nucleic acid–specific enzymes in molecular genetic analyses. One example is the polymerase chain reaction (PCR), where two oligonucleotide probes and a DNA polymerase are used to detect a nucleic acid sequence. In ligase-mediated detection reactions, pairs of DNA probes are joined by the action of a ligase. The joining event is used as a measure of the presence and nature of the nucleic acid sequences. This is possible because ligation critically depends on the ability of the probes to base-pair to a template nucleic acid molecule (Fig. 1). This assay mechanism has several valuable properties:

1. The ligation reaction is inherently very specific since it requires the coincident hybridization of two independent probe molecules immediately next to each other on a template. It is therefore

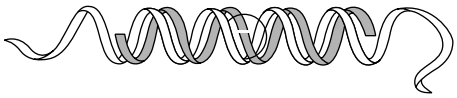

Fig. 1 Oligonucleotide ligation assay. Configuration of two oligonucleotide probes (shaded), hybridizing immediately next to each other on a target nucleic acid strand (white). Where the two probes meet (circled region), they can be connected by a ligase.

unlikely that the probes will join in the absence of the correct template nucleic acid molecule. As a consequence, the assay permits detection of unique nucleic acid sequences in complex populations of DNA molecules, for example, the complete human genome.

2. Variants of sequences can be conveniently distinguished because ligation is strongly inhibited by a mismatch even in a single nucleotide position at the junction of the probes.
3. The act of ligation of probes gives rise to a new DNA sequence not previously present in the reaction. This circumstance can be exploited for detection of the reaction products. For example, detection can be enhanced by exploiting the increased hybridization stability of the ligation product as compared to that of each individual probe. Alternatively, pairs of probes may be used in which one member carries a detectable moiety and the other is bound to a support before or after the ligation assay. Thereby, ligation products can be efficiently isolated and excess probes removed by washes before detection. If the two ligatable probe sequences are located at either end of the same DNA molecule, then the ligation will result in a circularized probe, wound around the target molecule. Finally, ligation products can also be recruited as templates in subsequent nucleic acid-amplification reactions, resulting in highly sensitive detection of target sequences.

Ligation-mediated analysis has undergone a strong development from the characterization of ligase enzymes and the first analytical ligase experiments carried out in the late 1960s and early 1970s, respectively. We will first discuss some fundamental properties of ligation reactions before describing some of the methods that have been developed on the basis of the probe ligation principle.

1.2 Biology of Ligation

Ligases are proteins that serve to join the ends of polynucleotide strands. They use cofactors such as NAD or ATP to supply the energy required to form the phosphodiester bonds. By contrast, the so-called breakage-reunion enzymes, exemplified by the topoisomerases, first break and then reseal DNA strands in a concerted fashion, and do not require an external supply of energy.

In the cell, ligases complete excision-repair reactions in damaged DNA. In addition, they seal interrupted DNA strands during discontinuous DNA replication, and during meiosis they participate in altering the continuity of paternally and maternally inherited DNA sequences through genetic recombination.

The first biochemical characterization of enzymes that join DNA strands appeared in 1967. The isolated ligases soon proved to be of great value as biotechnological tools for the analysis of DNA structure and construction of novel DNA molecules. Using

these enzymes, it famously proved possible to assemble recombinant molecules from separate DNA segments *in vitro*, and then clone, propagate, and express these genes in new organisms.

1.3 Properties of Ligases

Several enzymes are available that can join nucleic acid strands in a template-dependent manner. The DNA ligase most commonly used in laboratory work is derived from bacteriophage T4. T4 DNA ligase is a monomeric protein with a molecular weight of 68 kDa. It uses ATP as a cofactor and can join both DNA and RNA strands, provided that these are immediately juxtaposed by being base-paired to complementary strands, which can be either DNA or RNA. Reactions involving RNA strands proceed much less efficiently, however. Ends of double-stranded DNA molecules can be joined by the T4 DNA ligase, even when these have no single-stranded extensions that can hybridize and thus stabilize the interaction between the two ends.

The *E. coli* ligase has a molecular weight of 74 kDa. Unlike the ligases derived from bacteriophages, archaea, and eukaryotes, all of which use ATP as a cofactor, the *E. coli* ligase requires NAD as a cofactor, as is true for other bacterial ligases.

Ligases have also been isolated from thermophilic organisms such as *Thermus thermophilus*, *Thermus aquaticus*, and *Desulfurolobus ambivalens*. These enzymes operate at high reaction temperatures and survive conditions that denature DNA. At the optimal reaction temperature of these enzymes, oligonucleotides are less likely to interact with mismatched target sequences. Furthermore, the thermostable ligases exhibit no or little tendency to join DNA molecules with base-paired (blunt) ends or with short complementary (sticky) ends. Because of these properties, they offer increased selectivity of detection and convenience in many analytical reactions.

T4 DNA ligase can also be employed to construct nucleic acid strands that branch into two distinct 3′ end sequences by attaching the 5′ phosphate of an oligonucleotide to the 3′ hydroxyl of a nucleotide residue internal to another oligonucleotide. This requires that this second oligonucleotide is constructed such that the internal nucleotide is connected to the downstream sequence by a 2′ to 5′ phosphodiester bond, rather than the regular 3′ to 5′ bond, leaving a free 3′ hydroxyl.

In contrast to the enzymes just mentioned that all require double-stranded substrates, the T4 RNA ligase joins DNA or RNA strands that are not base-paired to a complementary polynucleotide strand. The probability of ligation is increased, however, if the two ends to be ligated are positioned near each other. This enzyme requires ATP as a cofactor.

1.4 Chemistry of Enzymatic Ligation

DNA ligases join DNA strands by using the energy of a pyrophosphate linkage in a nucleotide cofactor to create a new phosphodiester bond, connecting the two strands. This bond is formed between a 5′-phosphate group and a 3′-hydroxyl on two adjacent nucleic acid molecules. The enzyme-catalyzed reaction can be described in four steps (Fig. 2): first, a high-energy enzyme intermediate is formed when an adenylyl group from a cofactor (ATP or NAD) is coupled to the ligase while releasing pyrophosphate

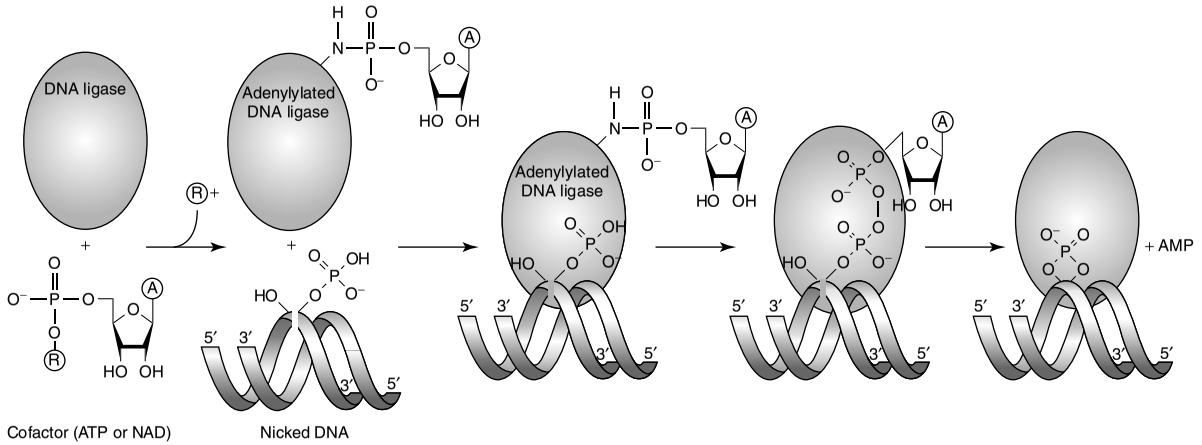

Fig. 2 The chemistry of enzymatic ligation of nucleic acids. The reaction takes place in four reversible reaction steps. In the first step, an adenylyl group from a cofactor, NAD or ATP, is transferred to the ε-amino group of a lysine residue in the DNA ligase enzyme. Thereby the energy required to join two nucleic acid strands is transferred from the cofactor and stored temporarily in the form of a high-energy bond between an adenylyl group and the enzyme. The activated ligase then binds to a nicked site on a DNA duplex. Next, the adenylyl group is transferred to the 5′-phosphate to be connected to the 3′-hydroxyl by ligation. This step recreates a pyrophosphate linkage and preserves the high-energy bond. Finally, the activated 5′ end is attacked by the nearby 3′-hydroxyl group, resulting in the formation of a phosphodiester bond between the 5′ and 3′ ends and releasing AMP. The circled A indicates an adenine group and the circled R represents either a pyrophosphate (in the case of the cofactor ATP) or nicotinamide mononucleotide monophosphate (in reactions in which NAD is a cofactor).

or NMN. The adenylylation occurs at a lysine residue in a conserved motif in the ligase. In the second step, the activated enzyme binds to a nicked site in the substrate. The adenylyl group is then transferred to the 5′-phosphate at the nick, and finally this activated phosphate is attacked by a nearby 3′-hydroxyl group, forming a phosphodiester bond between the two adjoining strands and AMP is released. The enzyme remains bound to the ligation center throughout the ligation process and recognizes the adenylylated phosphate moiety together with the nearby 3′-hydroxyl. Probably, the reactivity of the activated 5′-pyrophosphate is further increased by bridge complexation to the enzyme via a magnesium ion required in the reaction.

1.5 Substrate Requirements in Enzymatic Ligation Reactions

In contrast to the ligation of restriction enzyme–digested DNA fragments, probes in ligation assays generally hybridize stably under assay conditions. The reaction is therefore more similar to the sealing of an interrupted DNA strand in a duplex molecule. However, since the ligation reaction can trap hybridized molecules through the formation of a covalent bond, it is also possible to use short oligonucleotide probes involving just a few hybridizing bases in ligation assays. By contrast, such short probes would exhibit very limited stability in conventional hybridization-based assays.

As mentioned earlier, either RNA or DNA molecules can be used as probes in reactions catalyzed by T4 DNA ligase, although most commonly, DNA oligonucleotides are employed. Enzymatic ligation requires the presence of a phosphate group at the 5′ end of one probe molecule to be joined to a hydroxyl group at a nearby 3′ end. Ligases are very sensitive to mismatches at the nucleotides on either side of the nick to be sealed (Fig. 4). A mismatch at the 3′ end generally is more inhibitory than one at the 5′ end. Mismatches in other positions of the probe-target hybrid can also significantly reduce the efficiency of ligation. The *Tth* DNA ligase has been shown to ligate substrates with a mismatch nine nucleotides away from the nick in the 5′-direction with a lower efficiency than the corresponding matched substrate. Ligases also require a minimal length of base-paired sequences, which differs between enzymes. As an example, T7 DNA ligase is able to join a 5′ hexamer to a nonamer, while *Tth* DNA ligase is not.

1.6 Ribozyme Ligases

RNA molecules have been found that have the capacity to catalyze ligation of two RNA molecules hybridizing in juxtaposition on a complementary nucleic acid molecule. Such ribozyme ligases have been isolated from large pools of combinatorially synthesized RNA sequences by an iterative process of *in vitro* selection for the ability to ligate themselves to another RNA molecule, and amplification of ligation products. Molecules with a ligation capacity greatly increased over background levels were isolated and sequenced. Nonetheless, RNA ligases remain substantially less efficient than the protein enzymes.

1.7 Chemical Ligation

Also, chemical means can be employed to join nucleic acid strands through a

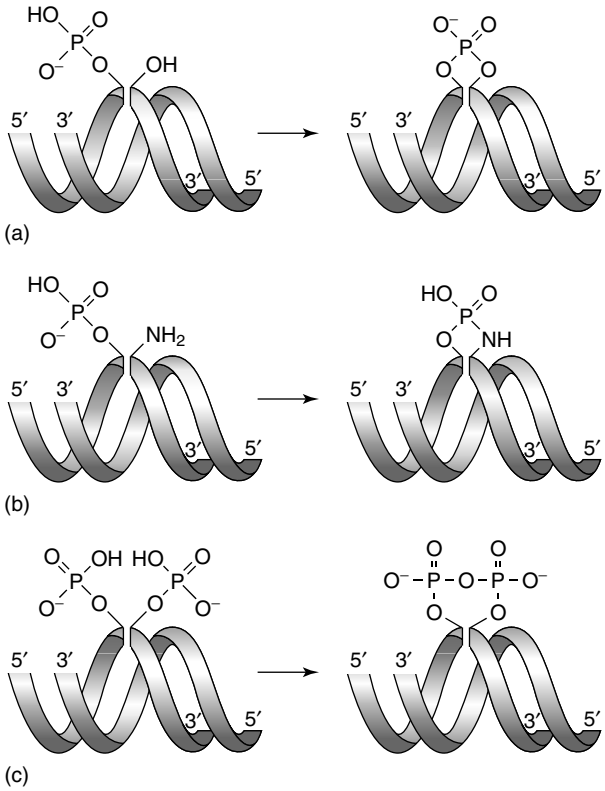

Fig. 3 Chemically induced nucleic acid ligation reactions. Using reagents such as cyanogen bromide or carbodiimide, nucleic acid molecules that are not substrates for the protein enzymes may be joined by chemical ligation. Examples of such reactions are (a) a strand with a 5′-hydroxyl group can be joined to a 3′ phosphate on a nearby strand to form a regular phosphodiester linkage; (b) a 3′ amino function may be joined to a 5′ phosphate, creating a phosphoamide linkage; and (c) two adjoining ends, both bearing phosphate groups, may be joined to form a pyrophosphate linkage.

phosphodiester linkage in a template-dependent manner. Substrate requirements in these reactions may differ from those of enzyme-catalyzed reactions (Fig. 3). For example, cyanogen bromide preferentially participates in the ligation of strands with a 5′-hydroxyl and a 3′-phosphate group, respectively, while protein ligases strictly require a 5′-phosphate group and a 3′-hydroxyl group. It is also possible to modify the ends of nucleic acid molecules so that they can be joined covalently upon hybridization to a template strand, but with no requirement for enzymes or catalysts. For example, upon hybridization of a 3′-phosphorothioate next to a 5′-iodothymidine residue, the two strands will be ligated, forming a phosphorothioate bond.

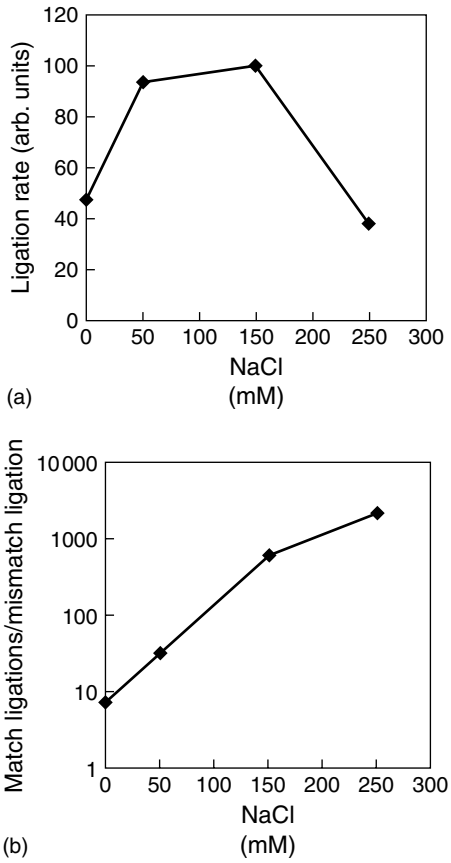

Fig. 4 Ligation at different concentrations of NaCl of two oligonucleotide probes using T4 DNA ligase under limiting conditions. (a) The rate of ligation in the presence of a template oligonucleotide fully matched to the probes. (b) The ratio of the number of ligations on a matched template to the number of ligations on a template mismatched at the position opposite the 3′ ultimate nucleotide at the site of ligation.

Also, pairs of oligonucleotides that form an interrupted third strand in a triple helix by binding to the major groove of a DNA duplex may be joined chemically. Since there is no requirement for substrate recognition by an enzyme, chemical ligation is not limited to the joining of natural nucleotide residues; residues containing other sugars or bases may become covalently joined to nearby strands. Moreover, besides phosphodiester bonds, phosphoroamide, phosphorothioate, and pyrophosphate bonds may be created. It is also possible to join fragments that are shorter than what is required by ligase enzymes. Chemical ligation thus extends the repertoire of substrate molecules that may be joined by ligation.

Because of the properties of nucleic acid-ligation reactions discussed above, ligation reactions have proven useful in a number of assays for analysis of target molecules. Next, we will describe some of these assays.

2 Techniques

2.1 Oligonucleotide Joining Reactions for Detection of Nucleic Acids

Ligation of pairs of oligonucleotide probes was used by Khorana and coworkers in the early 1970s to identify target molecules. Since the end of the 1980s, this has become a popular mechanism for genetic analyses, with the demonstration that DNA sequence variants can be efficiently detected and distinguished by comparing the ligation of pairs of probes that are matched at the junction to one but not the other of two target sequence variants. Over a wide range of ligase concentrations, this oligonucleotide ligation assay (OLA) reaction is inhibited by a single mismatched base pair where the two

strands to be joined abut. This mechanism is now in routine use in clinical diagnostics.

The amount of signal achieved from an OLA reaction performed on genomic DNA samples is generally not sufficient for unambiguous detection. This can be solved by generating more targets, more ligation events per target, or by amplifying the signal after ligation. More targets can be generated by performing a PCR amplification before ligation. If a thermostable ligase is used, thermal cycling may also be employed during the ligation to allow ligated pairs of probes to dissociate from their targets, giving room for new probes to hybridize and be ligated. In the ligase chain reaction (LCR), these two methods are combined. A second pair of probes, complementary to the first pair, is introduced. The ligation of the first pair of probes generates a template for the second pair and *vice versa*. In this manner, thermal cycling of the ligation reaction results in an exponential increase of ligated probes. The method is associated with a tendency to template-independent probe ligation through blunt-end ligation of the probe pairs. This problem can be avoided by using a gap-fill approach, where a gap of one or a few nucleotides first has to be filled in by the action of a polymerase before ligation can occur. The extension can be performed in an allele-specific manner by designing the 3′ ends of the probes to be extended so that they will be correctly matched to one but not the other of the target sequence variant.

A gap-fill polymerization step may also be included in the OLA test to decrease the number of probes required for an assay. In the regular OLA outlined above, the ability of one locus-specific probe to be joined to two different allele-specific probes is investigated. If the probes instead leave a gap corresponding to the variable position, then combined polymerase extension and ligation reactions can be performed in the presence of either allele-specific nucleotide triphosphate. With this method, allele distinction occurs at two levels; first the right nucleotide has to be introduced, and if a mistake is made, the ligation step will still be inhibited. Also, the number of probes that have to be constructed is decreased, at the cost of performing multiple reactions.

As mentioned, signal amplification can also be performed after ligation. This is most commonly done by introducing primer sequences in the probes so that ligation products can be amplified by PCR. Another amplification method is ligation-initiated Qβ amplification. In this reaction, the bacteriophage Qβ replicase enzyme, which has the capacity to replicate certain RNA molecules and then copy both the original strand and the replication product, is used. With this enzyme, a 10^9-fold amplification can be achieved in 30 min. To use this enzyme in a ligation assay, two RNA probes are constructed in such a way that they form a substrate for the Qβ replicase only after ligation to each other.

Several methods are available for detection of the ligated probes. For example, the members of the probe pair can be modified so that the reaction results in a detectable combination of functions in the ligation product. One of the probes may be biotinylated while the other probe carries a fluorophore, allowing ligation products to be captured on a support and detected. In another method, the remote ends of the ligation probes have complementary sequences carrying two different fluorophores. Upon ligation, the probes

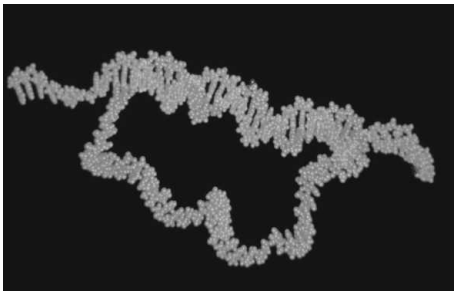

Fig. 5 A padlock probe, designed to be ligated into a circle upon interaction with the proper target sequence. The two ends of the linear probe (yellow) hybridize in juxtaposition on the target sequence (blue). The 5′-phosphate group on one end of the probe about to be joined by ligation to the 3′-hydroxyl at the opposite end is shown in red. Circularized molecules are wound around the target strand and can detach only by strand breakage or by sliding off a nearby end on the target molecule (see color plate p. xxii).

assume a hairpin-loop structure, and exhibit an altered emission spectrum due to the closeness of the two fluorophores. The method has been shown to permit analysis of point mutations in unamplified genomic DNA.

Since any nucleotide mismatches can be distinguished from perfect matches under standard reaction conditions, the oligonucleotide ligation procedure is suitable for automation and can be performed on large series of samples. The throughput of such analyses can be further increased by multiplexing – using many pairs of probes in the same reaction. The detection method must then be adjusted to separate the signals from different pairs of probes. For example, one of the probes of each pair may be size-coded to distinguish different loci by electrophoresis, while the other may be labeled with different fluorophores to identify separate alleles. The method has also been used to measure the copy number of genes. Alternatively, the locus may be represented by a hybridization sequence tag on one probe. Ligation products may be identified after hybridization to DNA microarrays with complements of the tag sequences. With this strategy, it is possible to identify large numbers of genotypes from a single reaction.

2.2 Padlock Probes

In a variant of the OLA technique, the two probes to be joined are in fact the two ends of the same linear probe molecule. Upon hybridization to the target sequence and subsequent ligation, the probe becomes circularized, wound around the target molecule in a padlock-like fashion (Fig. 5). Padlock probes may also be used in a gap-fill reaction to decrease the number of probes required for genotyping by half. If the target has no free ends, then ligated padlock probes will remain linked to the target even after denaturing washes. Thus, in solid-phase assays, unligated probes and any intermolecular ligation products may be efficiently washed away, reducing background signals. The topological link allows padlock probes to be used for localized detection of target DNA or RNA sequences via detectable moieties attached to the probe (Fig. 6).

Besides localized detection, padlock probes also offer particular advantages in multiplex assays. As more probes are combined in one reaction, the risk increases for unwanted ligation between different probes, fortuitously hybridizing next to each other somewhere in the added DNA sample. These ligation products

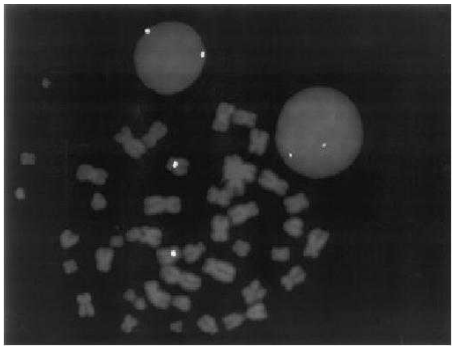

Fig. 6 *In situ* analysis of a repeated DNA sequence, located in the centromeric region of human chromosome 12, using a biotin-modified padlock probe, detected via fluorescein-conjugated streptavidin.

can be ignored, however, since properly ligated padlock probes can be conveniently distinguished from products of inter-probe ligations: Correct ligation of padlock probes results in circular molecules, while ligation of noncognate probe ends results in linear molecules that may be degraded by exonucleolytic treatment, and that fail to template rolling circle replification, as described below.

After ligation, circularized padlock probes may be amplified by PCR across the ligation junction, allowing thousands of different amplification products to be identified by hybridizing to tag microarrays. Circularized padlock probes are also suitable templates for rolling circle replication (RCR) reactions. This reaction is a linear amplification procedure that requires a single primer, and it results in long, single-stranded products that consist of many complements of the DNA circles repeated in tandem. The RCR reaction allows precise quantification and may be monitored in real time by the use of molecular beacons.

The hyper-branched rolling circle amplification (HRCA) reaction is a variant of the RCR procedure that allows a rapid isothermal amplification of circularized probes. Two primers are used; one primer complementary to the circular DNA strand and another one that hybridizes to each complement of the circle in the RCR product. Extension products from the primers along a strand catch up with each other and result in strand displacement of the downstream sequence. This process, in turn, generates new single-stranded sequences where new primers can anneal. The extension and strand displacement process yields a mixture of single- and double-stranded fragments of lengths representing multiples of the starting DNA circle. The amplification reaction is capable of billionfold amplification in a 90-min isothermal incubation. By using distinct primers for allele-specific padlock probes, the HRCA reaction has been used for genotyping.

Padlock probes have also been used to recognize specific target sequences in double-stranded DNA molecules. This can be done by first using PNA (peptide nucleic acid) probes that pry open the DNA duplexes, allowing padlock probes to be attached as the so-called ear ring probes. A similar effect has been achieved with linear probes having midsections that form triplex structures with duplex target DNA molecules. The probes become topologically linked to the target molecules when an oligonucleotide is added that allows the free ends of the probes to be joined. The mechanism has been used to couple

targeting peptides or biotin molecules to plasmid molecules.

2.3 Proximity Ligation

Also, proteins and other macromolecules can be detected via DNA ligation reactions using the so-called proximity ligation method. Pairs of binding reagents, such as antibodies or DNA aptamers binding separate determinants on a specific target protein, bring into proximity the 5′ and 3′ ends of oligonucleotides attached to the binding reagents (Fig. 7). By introducing a ligation template, referred to as a connector oligonucleotide, the DNA sequence extensions of proximity probes that have bound the same target molecule can be joined, forming a DNA strand with sequence elements required for amplification, identification, and visualization. By contrast, 5′ and 3′ ends on probes that have failed to bind in pairs to a target molecule rapidly hybridize to one connector oligonucleotide each, preventing any subsequent hybridization to a common connector and ligation. The method can be performed without any washes and offers a sensitivity that is orders of magnitude greater than conventional sandwich ELISA protein detection assays. Both individual and interacting proteins can be demonstrated. The method can also be performed in solid-phase mode for further increased sensitivity of detection, and more recently a variant of the method has been shown to permit sensitive detection of the location of target proteins *in situ*.

2.4 Other Uses of Ligation Reactions

Ligation reactions have also been used to detect bending and twisting of short double-stranded DNA molecules. By studying the efficiency with which a ligase joins the ends of DNA double helices to form circles, nucleotide sequence-dependent or protein-induced bending of the stiff double-stranded DNA molecule may be estimated. In a similar fashion, binding by transcriptional factor complexes can juxtapose separate regulatory gene sequences, allowing otherwise remote DNA fragment ends to be brought together and be ligated.

3 Outlook

Large-scale SNP genotyping studies currently appear to shift from hybridization- and polymerization-based assays to assays that also include a ligation step. Gene expression profiling may well follow the same trend. Furthermore, the proximity

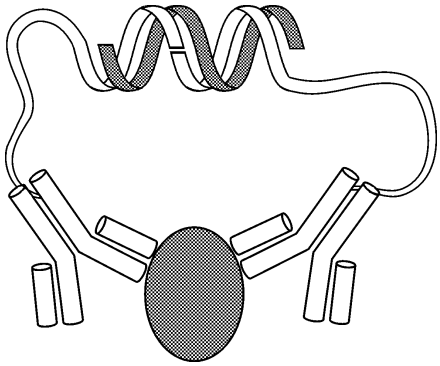

Fig. 7 Proximity ligation. Two proximity probes (white), consisting of antibodies conjugated to oligonucleotides, simultaneously bind to the same target protein molecule (dark shaded). Thereby an oligonucleotide (light shaded) and a ligase, added to template ligation of the two probes, can direct the formation of a DNA strand that can then be amplified and detected to reflect the presence of the target protein.

ligation mechanism can similarly transform large-scale protein expression and interaction studies to a form where DNA strands are created that represent the recognized proteins, and that can be amplified and detected, for example, after hybridization to tag microarrays. The unique event of a ligation reaction connecting two previously separate DNA sequences, or the two ends of individual probe molecules, can be designed to reflect the presence of target DNA, RNA, or protein molecules with excellent specificity, efficiently distinguishing closely similar target molecules. Once formed, the ligation products serve as a class of universally amplifiable, information-carrying molecules. They can therefore be detected with great sensitivity and allow very large numbers of target molecules to be investigated in parallel. In a similar manner, the probe ligation mechanism will also be important to demonstrate the location or the colocation of target molecules in biological specimens. In conclusion, ligation reactions are promising as a general means to investigate large, diverse sets of target molecules, and they may thus serve as the *molecular transistors* that will be required to standardize, miniaturize, and scale-up biological analyses for future highly resolving biological investigations in research, and in a wide range of application areas.

Keywords

Apolipoproteins
Proteins associated with the plasma lipoproteins.

Chylomicrons
A class of triglyceride-rich lipoproteins of intestinal origin, isolated by ultracentrifugation at a density of 0.93 g mL^{-1}.

HDL
High-density lipoproteins: density range 1.063 to 1.21 g mL^{-1}.

IDL
Intermediate-density lipoproteins: density range 1.006 to 1.019 g mL^{-1}.

Kringles
Named from their resemblance to Danish pretzels, these triloop peptide domains of 80 to 90 amino acid residues are held rigidly together by three internal disulfide bonds in a 1–6, 2–4, 3–5 pattern. They are found in a number of proteins including apolipoprotein (a), prothrombin, factor XII, plasminogen, tissue plasminogen activator, and urokinase.

LDL
Low-density lipoproteins: density range 1.019 to 1.063 g mL^{-1}.

VLDL
Very low-density lipoproteins, a class of triglyceride-rich lipoproteins: density range 0.93 to 1.006 g mL^{-1}.

Abbreviations

CE	Cholesteryl ester
CETP	cholesteryl-ester transfer protein

LCAT	lecithin:cholesterol acyltransferase
LPL	lipoprotein lipase
LRP	LDL-receptor-like protein
MTP	microsomal triglyceride transfer protein
FFA	free fatty acids
PLTP	phospholipid transfer protein
PPAR	peroxisome proliferator-activated receptor
SREBP	sterol regulatory element binding protein
TM	transmembrane

Lipoprotein metabolism can be subdivided into transport of exogenous lipids, transport of endogenous lipids from the liver to peripheral tissues, and reverse cholesterol transport with eventual excretion of cholesterol and its catabolic end products, bile salts, into the bile. Lipids are transported through the bloodstream as macromolecular complexes called *lipoproteins*, of which there are a number of classes that can be separated by sequential ultracentrifugation. Lipoprotein particles consist of a hydrophobic lipid core that is stabilized by a monolayer of phospholipids, free cholesterol, and apolipoproteins. Nine apolipoproteins are members of a multigene family. Eight of these are clustered at two loci: apoA-I, apoA-IV, apoA-V, and apoC-III on chromosome 11; and apoC-I, apoC-II apoC-IV, and apoE on chromosome 19. The *apoB* gene codes for two major structural proteins, one of which is produced by a novel mRNA editing mechanism.

There are an increasing number of key genes recognized that play important roles in lipid metabolism and transport. Those that code for intracellular proteins involved in cholesterol synthesis, storage, or catabolism include HMGCoA synthase (HMGCS1), HMGCoA reductase (HMGCR), acyl-CoA:cholesterol acyltransferase (ACAT1/SOAT1 and ACAT2/SOAT2), and cholesterol 7α-hydroxylase (CYP7A1). The diacylglycerol O-acyltransferases (DGAT1 and DGAT2) are important in triglyceride synthesis. The microsomal triglyceride transfer protein (MTP) is a major participant in the assembly of very low density lipoproteins (VLDL). There is a family of lipoprotein receptor genes, most notable of which is the LDL receptor. Similarly, there is a family of lipases including lipoprotein lipase (LPL), hepatic triglyceride lipase (LIPC), and endothelial lipase (LIPG). In addition to the apolipoproteins, but also associated with lipoproteins, are a number of gene products that are important for lipid transport. These include lecithin:cholesterol acyltransferase (LCAT), phospholipid transfer protein (PLTP), and cholesterol ester transfer protein (CETP). Key genes involved in reverse cholesterol transport are ATP-binding cassette A1 (ABCA1), scavenger receptor SR-BI/CLA1 (SCARB1), and caveolin (CAV1). Other members of the ABC transporter family are being increasingly seen as major players in lipid transport. For example, ABCA7 and ABCB4 are phospholipid transporters, and ABCB11 is the bile salt export protein.

Over the last decade, a number of nuclear receptors that regulate the genes mentioned above have been identified. These include the sterol regulatory element

binding proteins (SREBPs), the liver X receptors (LXRα, NR1H3, and LXRβ, NR1H2), the farnesoid X receptor (FXR, NR1H4), and the peroxisome proliferator-activated receptors (PPARα, PPARγ, and PPARδ).

Recent advances in molecular cell biology and molecular medicine, involving studies of these genes and their products, have significantly increased our understanding of lipoprotein metabolism and atherosclerotic heart disease.

1 Lipid Transport and Disorders

1.1 Exogenous Transport

Exogenous transport, illustrated in Fig. 1, describes the mechanism by which large quantities of dietary triglycerides and cholesterol are moved through the blood for storage. Prior to absorption, triglycerides are hydrolyzed by lipases to fatty acids and β-monoacylglycerol. The lipids are absorbed in the small intestine with the aid of emulsifying bile acids. Triglycerides are resynthesized and much of the cholesterol is esterified in the enterocytes.

1.1.2 Chylomicron Assembly

The hydrophobic triglycerides and cholesterol esters are packaged in the smooth endoplasmic reticulum (ER) of enterocytes as large stable microemulsion particles called *chylomicrons*. The nascent chylomicrons, many over 100 nm in diameter, are exocytosed *via* the Golgi apparatus into the lymphatics, whence they migrate through the thoracic duct into the blood. In addition to a single molecule of the structural protein apoB-48 they contain, primarily, apoA-I, apoA-II, and apoA-IV. As a result of exchange with HDL they lose the A apolipoproteins and gain C apolipoproteins.

The large polypeptide subunit of microsomal triglyceride transfer protein, which has homology to vitellogenin, is an 88-kDa protein the gene for which, *MTP* (chromosome 4q24), is expressed in intestine and liver and is required for lipoprotein assembly. It can be shown, *in vitro*, to enhance the transfer of triglycerides, cholesteryl esters, and phospholipids between phospholipid membranes and to mediate the lipidation of apoB. The activity, present in the microsomal fraction, resides in a heterodimer of MTP with a 58-kDa multifunctionalprotein disulfide isomerase (PDI), which acts as a chaperone that ensures correct protein folding. The MTP promoter is regulated positively by cholesterol and negatively by insulin, the latter *via* the MAPK(erg) cascade. It contains the recognition sequences for AP-1 and for the liver-specific factors HNF-1 and HNF-4. It also contains a modified sterol response element (SRE) at −124 to −116 that binds SREBP. Negative response elements have been found for ethanol and IL-1 at −612 to −142, and −121 to −88, respectively. In a large population-based study, a functional SNP, −493 G/T, was not associated with lipoprotein levels or CAD risk. Other reports have been contradictory, showing either decreased or increased LDL cholesterol in subjects homozygous for the less common −493 T variant. The degree of impact of this SNP is thought to depend on the level of visceral

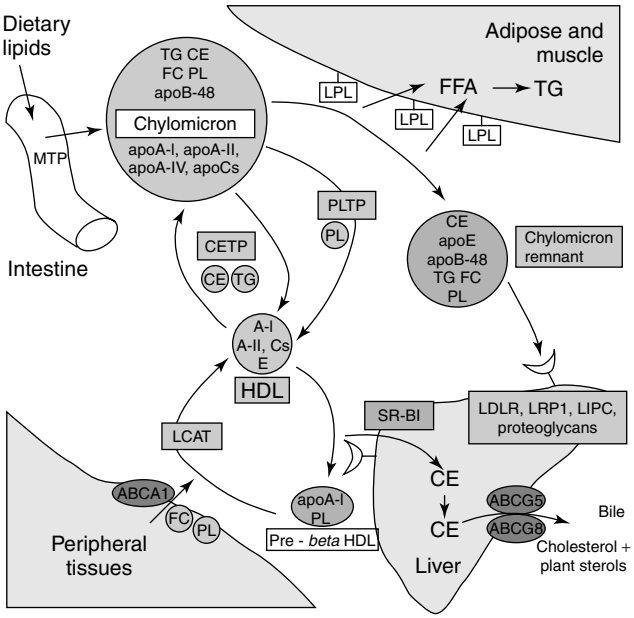

Fig. 1 Exogenous lipid transport (CE, cholesteryl ester; CETP, cholesteryl-ester transfer protein; FC, free cholesterol; LCAT, lecithin:cholesterol acyltransferase; LDLR, LDL receptor; LIPC, hepatic lipase; LPL, lipoprotein lipase; LRP1, LDL receptor-related protein 1; MTP, microsomal triglyceride transfer protein; FFA, free fatty acid; PL; phospholipid; PLTP, phospholipid transfer protein; SR-BI, scavenger receptor class B, 1; TG, Triglyceride.).

adipose tissue, and it may contribute to dyslipidemia in diabetes. The level of MTP mRNA was increased in both intestine and liver when hamsters were fed a high fat diet. The response was more rapid in the intestine.

1.1.3 Chylomicron Catabolism

1.1.4 Lipoprotein Lipase

Most of the triglyceride core of chylomicrons is hydrolyzed by the enzyme lipoprotein lipase (LPL), a triglyceride hydrolase that is synthesized at a number of sites, notably adipose tissue, skeletal muscle, heart, adrenal glands, placenta, and mammary gland. LPL, originally referred to as *clearing factor lipase*, is secreted from parenchymal cells and is transported to the vascular endothelial luminal surface where it attaches, as a noncovalent homodimer, to a high-affinity binding site. The precise nature of this interaction is unknown but is thought to involve cell membrane-anchored heparan sulfate proteoglycans such as perlecan, the glypicans, and the syndecans, and a specific heparin-sensitive binding protein. The hydrolysis of triglyceride releases free fatty acids (FFA) and β-monoacylglycerol. FFA are taken up by adipose tissue where they are re-esterified and stored as triglyceride. In other tissues, such as the heart, FFA can be oxidized as a source of energy. LPL can also facilitate the cellular binding and uptake of lipoproteins by lipoprotein receptors.

The gene for LPL (chromosomal location, 8p21.3) spans 30 kb, is comprised of 10 exons, and codes for a 475-amino acid-residue protein with a 27-residue signal peptide. Two sizes of mRNA, 3.35 and 3.75 kb, are observed. Under different physiological conditions, LPL is regulated hormonally primarily by post-transcriptional control. This control, in the case of insulin, is *via* stabilization of mRNA, and, with thyroid hormone and adrenaline, this is at the translational level. Regulatory cis-acting sequences and transcription factors responsible for basal promoter activity have been identified, as has a promoter region responsible for estrogen suppression of transcription. In adults, tissue-specific suppression of *LPL* gene expression in the liver involves the binding of transcription factor RF-2-LPL to a NF-1-like site in the region −591 to −288 of the transcription initiation site. The role of a peroxisome proliferator response element (PPRE), which binds peroxisome proliferator-activated receptors α or γ (PPARα and PPARγ) is enigmatic. Induction of PPARs with their ligands has been reported to either induce or suppress LPL transcription. A further complication is that changes in LPL mRNA do not always correlate with enzyme activity. An SRE at −90 to −81 that binds SREBP is responsible for the upregulation seen in adipose tissue as a result of cholesterol depletion. In tissues other than adipose or muscle, a positive response to sterols is mediated by an LXRα response element, a DR4 sequence in the first intron at +635 to +650.

The mature enzyme is a 421-residue, 55-kDa, N-linked glycoprotein. Ser132, Asp156 and His241 make up the active site, which is homologous to that in pancreatic, hepatic, and endothelial lipase. All these enzymes have a catalytic site pocket covered by a lid (LPL residues 216 to 239) that opens upon binding of the substrate. These structures play a vital role in determining the substrate specificity of each lipase. Unlike the other lipases in the family, LPL requires apoC-II as a cofactor. Asn43, an N-linked glycosylation site, is essential for catalysis and secretion of LPL. Sites in LPL have been identified that bind apoC-II and lipid. There are two sites rich in arginine and lysine residues, at 279 to 282 and 292 to 304, that bind to heparin.

The rare autosomal recessive disorder, familial lipoprotein lipase deficiency is characterized by diminished LPL activity and chylomicronemia. Numerous mutations in the *LPL* gene have been identified. Many are single-base substitutions; one is a 2-kb insertion and one a 6-kb deletion. Exon 5 appears to be a mutational hot spot, with numerous missense mutations that produce inactive LPL. Homozygosity for G188E or A221del, two of the most common mutations, causes chylomicronemia. Another relatively common mutant, N291S, decreases LPL activity, but is not severe enough on its own to cause chylomicronemia.

Four out of five cases of pregnancy-induced chylomicronemia were shown to be due to partial LPL deficiency caused by mutations in the *LPL* gene. In these subjects, hypertriglyceridemia became much more pronounced during pregnancy, when there is normally a much higher rate of production of VLDL.

Two SNPs in the *LPL* gene, −93 T/G and D9N, are in strong linkage disequilibrium in Caucasians and are associated with differences in the levels of plasma triglyceride. The Asn9 allele is present at a population frequency of 1.5%, with carriers having triglyceride values 25 mg dL^{-1} higher than noncarriers and a higher risk of heart disease. More common

is the S447X variant. The 447X allele, with a population frequency as high as 25%, is associated with decreased triglycerides and lower risk of vascular disease.

In transgenic mice expressing a high activity of human LPL in heart, skeletal muscle, and adipose tissue, the plasma levels of VLDL triglyceride were much decreased and HDL2 levels were raised. The clearance of VLDL and the conversion of VLDL to LDL were enhanced. There was no increase in VLDL levels in these animals after sucrose feeding as seen with normal mice. When placed on a high-cholesterol diet, the animals were protected against hypercholesterolemia.

1.1.5 Chylomicron Remnant Uptake

The fatty acids released by LPL are taken up by the surrounding tissue, a process facilitated by fatty acid transport proteins. They are stored as triglyceride, or used as fuel. Along with free cholesterol and phospholipid, apoC-II is shed, as the chylomicron particles get progressively smaller. During this process they acquire apoE and cholesterol esters, and lose most of the other apoproteins, except apoB-48, by transfer with HDL. Ultimately, chylomicron remnant particles rich in cholesterol esters are formed. These are rapidly removed at the microvillus surface of hepatocytes by a high-affinity process. Earlier it was thought that a distinct chylomicron remnant receptor existed. Despite much evidence for its existence it eluded purification and cloning. It is now accepted that the LDL receptor can initially bind to chylomicron remnants with apoE acting as the ligand. Remnants bound to the LDL receptor move rapidly to clathrin-coated pits at the base of the microvilli and are endocytosed. Hepatic lipase, which is bound to cell-surface heparan sulfate proteoglycans, is also involved in initial binding to remnants. The space of Disse is rich in apoE, which is also bound to the proteoglycans. The remnant particles accumulate apoE, increasing their affinity for the LDL-receptor-related protein or LRP1 (also referred to as the *α_2-macroglobulin receptor*).

LRP1 (Table 1) is a large multifunctional cell-surface receptor comprised of a large 515-kDa extracellular domain and an 85-kDa membrane-spanning subunit. It is expressed in a number of tissues including liver, adrenal cortex, ovary, fibroblasts, macrophages, and some neurons. In addition to binding to α_2-macroglobulin-protease complexes LRP1 has been shown to bind apoE-enriched βVLDL, Pseudomonas exotoxin A and plasminogen activator-inhibitor complexes. The binding and uptake of these ligands is blocked by a 39-kDa receptor-associated protein (RAP) that copurifies with the receptor. LRP1 binds with high affinity to the C-terminal domain of lipoprotein lipase (residues 378 to 423 of human LPL). Knockout of LRP1 is lethal to the embryo.

Another member of the lipoprotein receptor family, LDL receptor-related protein 2 (LRP2), also referred to as *glycoprotein 330 (gp330)* (Table 1), is expressed by the epithelial cells of a number of tissues. It is found mainly as a cell-surface protein concentrated in clathrin-coated pits and is structurally related both to the LRP1 receptor and to the LDL receptor. Like LRP1, LRP2 binds to RAP, LPL, and apoE-enriched βVLDL. It also binds with high affinity to apoJ. Because LRP2 binds LPL with high affinity, like LRP1, it may be involved in the hepatic clearance of LPL-associated lipoproteins. It is mainly expressed in specialized epithelial cells, particularly in proximal renal tubules. Whatever the precise role of LRP1

Tab. 1 Six human lipoprotein receptor genes.

and LRP2 in chylomicron remnant removal may be, evidence in mice suggests a greater role for the LDL receptor itself.

A recently recognized receptor expressed on monocytes, macrophages, and endothelial cells is the apolipoprotein B48 receptor (APOB48R), which is capable of binding apoB-48-containing triglyceride-rich lipoproteins. It is possible that this protein plays a role in the formation of foam cells in the artery wall.

1.2 Endogenous Transport

The transport of endogenous lipids, illustrated in Fig. 2, describes the movement through the circulation of lipids synthesized in the liver.

1.2.1 VLDL Assembly

The liver secretes triglyceride-rich lipoproteins analogous to chylomicrons. These nascent VLDL particles are smaller than chylomicrons but have a similar lipid composition. In humans, they contain one copy of apoB-100 as their structural protein as well as apoE and the A and C families of apoproteins. The triglyceride used for their assembly in the liver is derived from chylomicron remnants and from fatty acids released by LPL and taken up by the liver, or from fatty acids synthesized *de novo*. As with chylomicrons, MTP plays a critical role in the assembly of nascent VLDL. Unlike chylomicron secretion, which is maintained only throughout the postprandial period, VLDL production continues, albeit at a reduced rate, even during periods of starvation, when it is

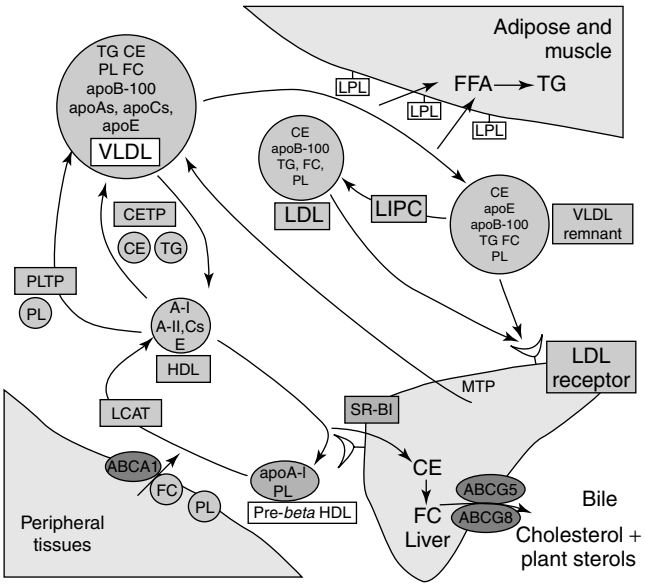

Fig. 2 Endogenous lipid transport (CE, cholesteryl ester; CETP, cholesteryl-ester transfer protein; FC, free cholesterol; LCAT, lecithin:cholesterol acyltransferase; LIPC, hepatic lipase; LPL, lipoprotein lipase; MTP, microsomal triglyceride transfer protein; FFA, free fatty acid; PL, phospholipid; PLTP, phospholipid transfer protein; SR-BI, scavenger receptor class B, 1; TG, Triglyceride.).

an important means of providing muscle fuel.

In the relatively common disorder familial combined hyperlipidemia (see Sect. 1.3.6), overproduction and secretion of VLDL particles by the liver is the cause of the increased level of circulating apoB and triglyceride. The important role of stearoyl-CoA desaturase (SCD), which catalyzes the formation of the monounsaturated fatty acids oleate and palmitoleate, in regulating the supply of triglyceride, phospholipid, and cholesteryl esters for VLDL production, has been recognized.

1.2.2 **VLDL Catabolism**

Nascent VLDL loses apoA-I and apoE and gains more C apoproteins by a process of exchange with HDL. The triglyceride core of the mature VLDL is hydrolyzed by LPL in a similar manner to chylomicrons, though at a slower rate.

As the hydrolysis of VLDL triglyceride proceeds, transfer with HDL restores apoE and removes most of the C proteins. The resulting VLDL remnants contain a single molecule of apoB-100 and several copies of apoE. About half the remnants are removed by the hepatic LDL receptor, which has high-affinity binding sites for apoE. The remaining remnants lose more triglyceride by transfer to HDL and by the action of hepatic lipase (LIPC), and are converted to LDL particles (Fig. 3) that are rich in cholesterol esters. During this process, the particle decreases in size to about 22 nm in diameter and the apoE and C proteins are lost, leaving apoB-100 as the sole protein.

Hepatic lipase has similar substrate specificity for triglycerides as LPL, but hydrolyses phospholipid two to three times more effectively. It is not activated by apoC-II and does not require Ca^{2+}. Like LPL, its optimum activity is at pH 8.0 to 9.0. Evidence points to a role for hepatic lipase, in addition to LPL, in the production of remnant particles that can be efficiently taken up by the liver. It contributes, *via* an interaction with extracellular proteoglycans, to the process of binding and uptake of remnants by the liver.

The gene for hepatic lipase (chromosome 15q21.3) is 35 kb in length and is composed of 9 exons. The promoter region has tissue-specific glucocorticoid and cAMP response elements. Thyroid hormone has been shown to increase the activity of hepatic lipase by a posttranslational mechanism. Mature hepatic lipase is a glycoprotein (60 kDa) of 476 residues. As a result of alternative splicing, the adrenal gland produces an isoform that is different from the liver enzyme. Four polymorphisms in the LIPC promoter, at −250, −514, −710 and −763, are in almost complete linkage disequilibrium. The rare haplotype, which has a frequency of 0.20, is associated with increased HDL levels, decreased hepatic lipase activity, and more buoyant LDL particles. Hence, LIPC variants play an important role in determining the amount of small dense LDL, which is believed to be associated with increased risk of CAD.

The VLDL receptor (Table 1), a cell-surface receptor that binds with high affinity to VLDL and cholesteryl ester-rich βVLDL, but not to LDL, was first cloned in rabbits. It is expressed in the heart, skeletal muscle, and macrophages, with less expression in lung, kidney, placenta, pancreas, and brain. In contrast to the LDL receptor, to which it shows a very high degree of homology, it is not expressed in the liver. The human VLDL receptor protein is 96% homologous to the rabbit receptor. The human gene gives rise to two forms of the receptor, one with five

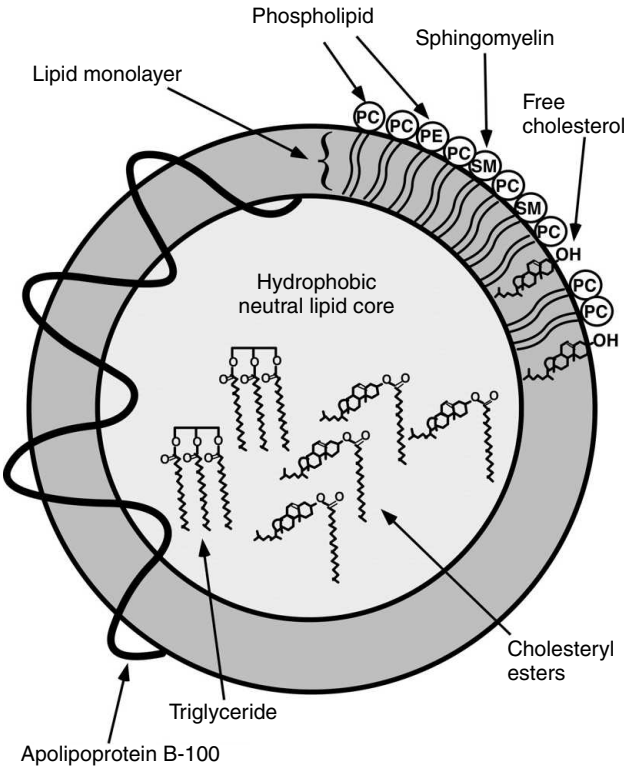

Fig. 3 Structure of low-density lipoprotein (PC, phosphatidylcholine; SM, sphingomyelin; PE, phosphatidylethanolamine.)

domains and one lacking the O-linked sugar domain. It is thought that the VLDL receptor functions in nonhepatic tissues in which fatty acids are actively metabolized. When compared to the LDL receptor gene, the VLDL receptor has an extra exon coding for a ligand binding domain. The VLDL receptor binds to triglyceride-rich lipoproteins *via* apoE, and not apoB, in concert with lipoprotein lipase (LPL), to which it also binds. Like the LDL receptor, it also binds to the receptor-associated protein (RAP). Its role in lipid metabolism has been hard to establish. Studies with VLDL receptor-deficient mice have been difficult to interpret, but it has now been shown that the VLDL receptor does indeed play a role in peripheral triglyceride hydrolysis. Another apoE receptor, homologous to both the LDL receptor and the VLDL receptor, is the low-density lipoprotein receptor-related protein 8 (LRP8) also known as the *apoE receptor-2* (APOER2). It binds with high affinity to apoE-rich βVLDL, and poorly to VLDL and LDL. LRP8 is expressed most highly in the brain and placenta. Both LRP8 and the VLDL receptor have neuronal signaling functions and play important roles during the development of the brain.

The LDL receptor is responsible for the uptake by the liver of VLDL remnants, the binding affinity of which is considerably

higher than that of LDL. The ligand on VLDL is apolipoprotein E (apoE).

1.2.3 LDL Catabolism

The liver removes approximately 70% of the LDL particles circulating in plasma, mainly *via* the LDL receptor: the remainder are removed by a nonspecific low-affinity process. On LDL particles the ligand for the receptor is apolipoprotein B (apoB).

The LDL receptor is present on the surfaces of most nucleated cells. The highest concentration of mRNA is in the adrenal gland followed by the corpus luteum of the ovary and then the liver. The half-life of LDLR mRNA in liver is 30 min.

The LDL receptor transcript, a 5.3-kb mRNA, has a long 2.5-kb 3′ UTR, which contains a dinucleotide AT repeat polymorphism. The gene has three 300-bp Alu repeats that may be a recombination hot spot.

The N-terminal 292 residues of LDLR, encoded by exons 1 to 6, make up the ligand binding domain with seven cysteine-rich tandem repeats. Each repeat of approximately 40 residues has three disulfide bonds with a coordinated Ca^{2+} ion. Exons 7 to 14 encode a domain that has a strong homology with the EGF precursor. This 400-residue region, which contains a six-bladed β-propeller motif, is central for endosomal release of the lipoprotein and for receptor recycling to the cell surface. A 50-residue O-linked sugar domain is encoded by exon 15. This is followed by a membrane-spanning domain of 22 residues encoded by exon 16 and the beginning of exon 17. The end of exon 17, and part of exon 18, code for a cytoplasmic C-terminus of 50 residues. This has a signal, NPVY, which is necessary for the incorporation of the receptor into clathrin-coated pits, and subsequent endocytosis. There is another motif between residues 790 and 839, which directs the receptor to the basolateral surface of hepatocytes. The remainder of exon 18 encodes the 3′UTR. At the low pH found in endosomes, the β-propeller region displaces lipoprotein particles bound to the receptor by means of a strong interaction with ligand-binding repeats 4 and 5.

LDL receptor activity is under sterol-dependent regulation, being tightly coupled to the extracellular level of LDL, with most of the regulation at the level of gene transcription. In addition to the major means of regulation by repression of transcription by sterols, the hepatic expression of the LDL receptor is stimulated by thyroid hormone. The proximal promoter of LDL receptor contains a sterol regulatory element (SRE) flanked on either side by Sp1 sites. For a high level of expression, the active form of SREBP acts in synergy with Sp1.

1.3 Disorders of Lipid Transport

1.3.1 Abetalipoproteinemia

The MTP protein and microsomal triglyceride transfer activity are absent in intestinal biopsies from patients with abetalipoproteinemia. In several subjects, this has been shown to be due to homozygous mutations in the gene for the large subunit of MTP. Abetalipoproteinemia is a rare autosomal recessive disease, which is characterized by the absence of apoB-containing lipoproteins in the plasma because of an inability to secrete triglyceride-rich lipoproteins from intestine or liver. The failure to absorb lipids results in a deficiency of the fat-soluble vitamins A, D, E, K and β-carotene. In the absence of dietary vitamin supplementation, this results in neurological and ophthalmological complications during childhood.

1.3.2 Hepatic Lipase Deficiency

Familial hepatic lipase deficiency, a rare condition, is marked by elevated levels of VLDL remnants and by the presence of triglyceride- and phospholipid-rich LDL and HDL. Compound heterozygosity for S267F and T383M is associated with high levels of cholesteryl-ester rich βVLDL in plasma, and premature atherosclerosis.

1.3.3 Familial Hypercholesterolemia

The discovery of the LDL receptor and its subsequent cloning has led to an understanding of the molecular basis of familial hypercholesterolemia (FH). FH is an autosomal codominant disorder characterized by elevated LDL levels, the presence of cholesterol deposits in skin and tendons (xanthomas) and in arteries (atheromas), and premature coronary heart disease (CAD). Clinical disease occurs earlier in men than in women. More extensive xanthomatosis and atherosclerosis are seen in homozygotes, who generally die of myocardial infarction (MI) by age 30. FH is caused by one of several hundred of the known mutations in the LDL receptor gene. The heterozygous frequency is 1 in 500 and the homozygous frequency 1 in a million. This monogenic disorder accounts for 4% of those individuals having type IIa hyperlipidemia as designated by the World Health Organization (those with LDL levels above the 95th percentile and with no other lipoprotein abnormalities).

A number of biochemical studies first led to the recognition that the LDLR receptor defects cause FH. Radiolabeled autologous LDL was found to have a lower fractional catabolic rate (FCR) when injected into FH subjects, when compared with normal individuals. Normally the half-life of LDL is 2.9 days whereas it is 4.7 days in heterozygous patients and 6.6 days in homozygotes. The slightly altered lipid composition of LDL prepared from FH patients did not affect metabolism of the LDL particles when injected into control subjects. Deficient high-affinity specific binding or internalization of LDL was seen in fibroblasts from FH homozygous patients. Kinetic studies indicated that, in addition to lower FCR, there is an increase in the rate of LDL production in FH. This is explained by a reduced rate of clearance of VLDL remnants by the LDL receptor, and a consequential increase in the proportion converted to LDL. The receptor normally clears VLDL remnants much more rapidly than it does LDL because of its higher affinity for apoE than for apoB. In a subset of FH patients the underlying mutation affects only LDL binding, and not that of VLDL remnants, and there is a more modest rise in plasma LDL levels.

Normally the liver takes up 70% of LDL particles through the LDLR, and the remainder through a less well-understood low-affinity nonspecific mechanism. This so-called *scavenger pathway* plays a more dominant role in the removal of LDL in FH. The scavenger pathway operates in macrophages in the artery wall where the cells take up modified LDL particles and can develop into the lipid-laden foam cells that are found in atheromas. Therefore, in FH, the longer residence time of LDL, which leads to more oxidation and other modifications of the LDL particles, is a factor underlying the observed premature CAD. This is especially true of homozygous patients.

A diagnosis of FH has come to be synonymous with LDL receptor gene defects, and many individuals so diagnosed can be

shown to have LDL receptor mutations. A few patients, though, do not, and defects at other loci can cause a phenocopy disorder. Where an LDL receptor mutation is known to be present, it has been occasionally observed that other loci can modulate its severity.

Five classes of LDL receptor defect have been established at the molecular level. Class 1 is null alleles caused by different types of mutations that result in the absence of protein synthesis and account for 17% of FH cases. Class 2, comprising the majority of cases (54%), is due to mutations that cause defective transport of the receptor from the ER to the Golgi apparatus, with most mutations occurring in repeats 4 and 5 of the ligand binding domain. Receptor molecules that do not bind normally even though they are found on the cell surface constitute class 3. Most of these are due to in-frame mutations that affect the EGF precursor homology or ligand binding domains. Class 4 mutations are found in the cytoplasmic domain and result in receptors that fail to endocytose due to an inability to cluster in clathrin-coated pits. Class 5 comprises another common set of mutations (22%). Here, binding and endocytosis are normal, but there is a failure to release the LDL particle in the endosomal compartment. Many of these are due to mutations in the β-propeller domain.

The *LDL* receptor gene has been targeted in mice using homologous recombination to produce an FH model. These Ldlr$^{-/-}$ mice have a twofold increase in cholesterol levels due to substantial increases in IDL and LDL, but do not develop substantial atherosclerosis. The addition of cholesterol to the diet accentuates the phenotype. The phenotype in these mice can be temporarily reversed using a recombinant LDL receptor adenovirus.

1.3.4 Familial Ligand-defective Apolipoprotein B-100

As stated above, FH accounts for only 4% of cases with elevated LDL and much effort has been made to identify other genetic loci that are involved, besides the LDL receptor. Autologous LDL, prepared from non-FH hypercholesterolemic patients, was often found to have a low FCR. It was surmised that this could be due to the presence of ligand-defective LDL, and patients were identified whose LDL showed poor binding to LDL receptors on cultured fibroblasts. Because the lipid composition of the LDL was unaffected, it was concluded that an abnormality in apoB due to a genetic defect was responsible. This autosomal codominant disorder is called *familial ligand-defective apoB* (FLDB).

After separation of the two LDL allotypes from one patient with FLDB the particles were shown to have more than 90% reduced affinity for the receptor. In three families, an apoB R3500Q mutation was shown to associate with FLDB. The R3500Q mutation, with a frequency in the general population of 1 in 600, is much more common among patients attending lipid clinics. The hypercholesterolemia seen with R3500Q heterozygotes is milder compared with that seen in FH heterozygotes, and the presence of xanthomas and premature CAD is less frequent. The few homozygotes that have been reported are more severely affected than heterozygotes. Two other FLDB mutations have been reported. The R3531C variant, which is less common than R3500Q, results in milder hypercholesterolemia, consistent with the finding that 3531C LDL particles retain 27% of normal binding affinity for the receptor. FH/FLDB patients with compound heterozygosity for apoB R3531C and LDL receptor P663L are more severely

affected than those with the FH mutation alone. The other known mutation, R3500W, is similar in its effects to the R3500Q disorder.

An interesting mechanism has been proposed to explain why the LDL particles are defective in FLDB. The topological arrangement of the apoB polypeptide on the LDL surface, mapped using monoclonal antibodies, displays a "ribbon and bow" structure. Mutations in the region around residues 3500 to 3531 cause conformational changes that disrupt the topology and mask the receptor binding site. A direct interaction between W4369 and R3500 probably helps to preserve the bow arrangement.

1.3.5 Familial Hypobetalipoproteinemia

Individuals with familial hypobetalipoproteinemia (FHB) have apoB mutations that result in the production of C-terminally truncated variants. The length of the truncated protein is monotonically related to the diameter and buoyant density of the lipoprotein formed. Numerous such mutations have been reported, many of which are small deletions. Four mutations that were predicted, B-2, B-9, B-25 and B-29 proteins, were not detected in plasma. B-31 was found only in the HDL density interval, whereas, B-37 was found in HDL, LDL, and VLDL intervals. Those longer than B-46 were found mainly in LDL and VLDL. Three mutants, B-75, B-87 and B-89, had increased binding to the LDL receptor. In one especially interesting case of FHB, a frameshift mutation created a sequence of eight consecutive adenines, caused by a single base pair deletion in exon 26 that predicted the formation of a truncated apoB species. However, this allele was shown to produce full-length apoB-100 in addition to the truncated protein. This was due to an additional adenine being inserted in a portion of the mRNA molecules during transcription, leading to restoration of the correct reading frame.

The phenotype associated with FHB is variable. Simple heterozygotes have low levels of LDL cholesterol but are usually clinically asymptomatic. At its most severe, with the presence of 2 null alleles, FHB is similar to the recessive disorder abetalipoproteinemia (see Sect. 1.3.1 above). Mouse models for FHB have been produced by targeting the *apoB* gene using homologous recombination.

1.3.6 Familial Combined Hyperlipidemia

An independent phenotype termed *familial combined hyperlipidemia* (FCH) was originally described, more than 30 years ago, in families of patients who had survived heart attacks. FCH was originally thought to be a dominant disorder, but more recently it has been shown to obey a multigenic mode of inheritance. It displays high penetrance and is present at a frequency of 1 to 2% in the general population. It is thought to play a role in 15% of cases of premature CAD. Any of three phenotypes can occur, and in any one individual the phenotype can vary over time. Because the genetic basis of FCH is not well understood, it is still identified by phenotype. Elevation of either VLDL or LDL level is seen in some subjects. However, levels of both these lipoproteins are elevated in most individuals with FCH. LDL cholesterol levels are almost always above 100 mg dL^{-1} and IDL is usually raised. High levels of apoB are a hallmark of this disease. Patients also tend to have HDL and LDL particles that are smaller, denser, and more atherogenic. There is much evidence that overproduction of VLDL, by about two-fold, is responsible for the observed dyslipidemia. Such overproduction

is thought to be due, in part, to an increase in flux of FFA to the liver. Obesity and insulin resistance, with elevated FFA, are often seen in cases of FCH. The molecular causes of FCH have proved difficult to decipher. Individual linkage studies of FCH families have identified genetic loci with high lod scores, but when data were combined from several studies the associations were considerably diminished, suggesting that FCH is caused by defects at alternate loci and may be multigenic. Thus, FCH is a genetically heterogeneous disorder, and there is evidence to support the involvement of several candidate genes. It has been suggested that the lipoprotein lipase gene plays a modifier role. A number of individuals with FCH have low LPL activity. A major candidate for FCH has been the ApoA-I/ApoC-III/ApoA-IV/ApoA-V locus at chromosome 11q23.3. Some, but not all, linkage studies have identified this locus. Other gene candidates are LCAT (see Sect. 2.3), CETP (see Sect. 2.5), manganese superoxide dismutase (an enzyme involved in lipid oxidation), intestinal fatty acid–binding protein 2 (FABP2), and tumor necrosis factor receptor superfamily, member 1B (TNFRSF1B).

1.3.7 Autosomal Recessive Hypercholesterolemia

The molecular basis of the rare disorder, autosomal recessive hypercholesterolemia (ARH), has recently been established. Defects in the LDL receptor and *apoB* genes were ruled out by cosegregation studies. ARH was mapped to chromosome 1p35–p36. This disease was originally referred to as *pseudo-homozygous FH*. The mean plasma cholesterol level of 29 patients was 561 mg dL^{-1}. The probands in two Sardinian families with this rare disorder had clinical symptoms that were analogous to those seen in the homozygous form of FH. One striking difference between ARH and FH was that fibroblasts from ARH patients bound and endocytosed LDL normally even though kinetic studies had shown decreased FCR for LDL. However, the degradation of LDL by monocyte-derived macrophages and EBV-lymphocytes isolated from ARH patients was defective. Normal processing of LDL was seen when the lymphocytes were transfected with the normal *ARH* gene, which codes for a receptor adapter protein. The ARH protein contains a phosphotyrosine binding domain (PTB). These domains bind to NPXY sequences found in the cytoplasmic tails of members of the LDL receptor family. The NPXY sequence targets receptors to clathrin-coated pits. One FH mutation, Y807C (in the *LDLR* gene) which results in defective internalization of the LDL receptor, disrupts the NPXY consensus sequence. Besides binding to the LDL receptor, the ARH protein binds to the receptor adapter protein AP-2, and the clathrin heavy chain. In some signaling proteins, PTB domains are essential for signal transduction. The ARH PTB domain is similar to that found in the two endocytic proteins, numb and Disabled-2 (Dab-2). It is likely that these two proteins, which are expressed in fibroblasts, can substitute for the ARH protein in those cells.

1.3.8 Autosomal Dominant Hypercholesterolemia

Besides FH and FLDB a third type of autosomal dominant hypercholesterolemia has been reported. In a large kindred with hypercholesterolemia, in which the LDL receptor and *ApoB* genes had been excluded, linkage was found to chromosome 1q32. The gene responsible for the disorder is *PCSK9*, which codes for the proprotein convertase subtilisin/kexin type 9.

This protein is mainly expressed in liver, kidney, and intestine. The missense mutations detected were thought to cause a gain of function. Its overexpression in mice results in a doubling of total serum cholesterol with no change in HDL. The related protease, PCSK8, cleaves and activates SREBP transcription factors.

1.3.9 Chylomicron Retention Disease and Anderson Disease

An inherited disorder of severe fat malabsorption was reported in 1961 and termed *Anderson disease*. A similar disorder, chylomicron retention disease (CMRD) was reported later, and differed from Anderson disease on the basis of partitioning between membrane-bound and cytosolic compartments of enterocytes, which accumulate large amounts of lipid in both cases. A variant of CMRD is associated with Marinesco–Sjogren syndrome, a neuromuscular disorder. All these diseases are characterized by failure to thrive in infancy, fat-soluble vitamin deficiency, low plasma cholesterol, and the absence of circulating chylomicrons. Hepatic secretion of VLDL appears to be normal. Recently, a coat protein complex, COPII, which facilitates transport from ER to Golgi, has been shown to be required for VLDL and chylomicron secretion. Mutations in the gene *SARA2*, which codes for the protein Sar1B, a GTPase component of COPII, have been shown to underlie Anderson disease and the two forms of CMRD.

1.3.10 Sitosterolemia

Sitosterolemia, also referred to as *phytosterolemia*, is a monogenic disorder that causes elevated levels of LDL. This rare autosomal recessive disease was first described over thirty years ago, and is characterized by highly elevated plasma levels of plant sterols, notably β-sitosterol and campesterol. By 1998, there were only 45 known cases of sitosterolemia. Plant sterols also accumulate in tissues, and are found in atherosclerotic plaque and in xanthomas, where they account for 20% of the sterol content. A characteristic of sitosterolemia is that during the first decade of life patients develop both tendon and tuberous xanthomas. Early CAD and MI are often associated with this disease.

In patients with sitosterolemia, although the absorption of cholesterol is only slightly higher than normal, that of plant sterols is dramatically elevated, from a normal 5% to between 15 and 63%. The underlying molecular basis for sitosterolemia remained a conundrum for decades. Both decreased hepatic *de novo* synthesis of cholesterol and HMGCoA reductase activity were seen. Conversion of cholesterol to bile acids was normal even though cholesterol 7α-hydroxylase activity was lower. There have been contradictory reports as to whether the cholesterol content of liver is affected. Considering that the increased absorption of sterols is insufficient to explain the levels of phytosterols in plasma, an important observation was that overall sterol excretion, particularly of plant sterols, into bile was low.

It has now been determined that mutations in one or the other of the ABC transporter genes *ABCG5* and *ABCG8* cause sitosterolemia. Mutations in the *ABCG5* gene were detected in only some of the patients. An inspection of the *ABCG5* locus at chromosome 2p21 revealed an additional ABC transporter, *ABCG8*. Mutations in the *ABCG8* gene account for the other cases of sitosterolemia. Both *ABCG5* and *ABCG8* are half transporters, each gene has 13 exons and codes for proteins (sterolin-1 and sterolin-2) each with one nucleotide binding fold (NBF) and a single transmembrane domain (TM) comprised

of 6 membrane-spanning α-helices. The genes are orientated in a head-to-head arrangement with the transcription start sites 140-bp apart. *ABCG5* and *ABCG8* interact to form a heterodimer in the ER, constituting a functional complex. In all cases, homozygous or compound heterozygous mutations were seen in either *ABCG5* or *ABCG8*. The presence of a single normal copy of each gene rules out the disease.

It seems that *ABCG5* and *ABCG8* have evolved as sterol transporters, which are expressed to the highest degree in liver and small intestine. When coexpressed they are found with apical plasma membrane markers. It is thought that an ER retention motif localizes these proteins in the ER until heterodimerization occurs, the motif is masked, and transportation to the Golgi proceeds. When these genes were overexpressed in mice, the animals had a decreased rate of net absorption of dietary cholesterol and an increased rate of excretion of sterol into bile. Contrary to what is seen in sitosterolemia, hepatic cholesterol synthesis was increased in these mice. With *ABCG5/ABCG8* knockout mice there was a higher fractional absorption of plant sterol from the diet and a high concentration of sitosterol in plasma.

2 Reverse Cholesterol Transport

The hepato-biliary system is the major means by which cholesterol is excreted. Whereas most of the bile salts and free cholesterol in bile are reabsorbed by the ileum and returned to the liver, a fraction is lost in the feces. Some of this is derived from cholesterol on remnant particles or from hepatic synthesis of cholesterol. The rest is from cholesterol returned to the liver from peripheral tissues by an active, specific mechanism. This latter process is termed *reverse cholesterol transport*. This is initiated in the extravascular compartment in cells of extrahepatic tissues, where free cholesterol effluxes with the aid of ATP-binding cassette transporter A1 (ABCA1) and the class B scavenger receptor SR-BI (see Sect. 7.1). In the case of ABCA1, especially in macrophages, an extracellular primary acceptor, pre-*beta*-1 HDL, comprised of phospholipid and two copies of apoA-I, takes up cholesterol. Pre-*beta*-1 HDL has an apparent molecular weight of 67 kDa. Some evidence also indicates that a lipoprotein particle with gamma electrophoretic mobility, containing only apoE, may also play a role. SR-BI facilitates the diffusion of free cholesterol between the plasma membrane and *alpha* HDL particles. Of the total efflux of cholesterol from peripheral tissues, possibly a greater amount is transferred by the SR-BI facilitated process than by the ABCA1 mediated one.

The cholesterol transferred to pre-*beta* HDL and *alpha* HDL is now a substrate for LCAT. The resulting cholesterol esters (CE) accumulate to form a hydrophobic core of larger pre-*beta* HDL particles and ultimately appear in large mature spherical HDL particles of alpha mobility. This CE can be taken up directly by liver *via* the scavenger receptor SR-BI, or transferred to LDL, VLDL, VLDL remnants, or chylomicron remnants by a process that is mediated by CETP.

Several subspecies of HDL are revealed by electrophoresis in nondenaturing gels and by isoelectric focusing. Some of these contain apoA-I but not apoA-II, and are referred to as *LpAI*. Others contain both of these proteins and are referred to

as *LpAI/AII*. LpAI and LpAI/AII play metabolically different roles, especially with regard to reverse cholesterol transport. Both are able to promote the efflux of cholesterol from the plasma membrane, but LpAI appears to mediate the translocation of intracellular cholesterol to the cell surface. LpAI/AII is the preferred substrate for hepatic lipase. The level of LpAI in plasma is a better measure of the protective antiatherogenic potential of HDL than LpAI/AII is.

2.1 ATP-Binding Cassette Transporter A1

Phospholipids can move readily (''flip-flop'') across the bilayer of certain membranes such as those of the endoplasmic reticulum. However, in the plasma membrane (and also late Golgi, endosomal and bile canalicular membranes) such passive equilibration is restricted and requires an ATP-dependent process involving members of a superfamily of ATP-binding cassette transporter proteins. Unlike the half transporters, ABCG5 and ABCG8, referred to above (Sect. 1.3.10), ABCA1 is a full transporter with 2 TM and 2 NBF domains. ABCA1 is highly expressed in liver where it is involved in the secretion of nascent HDL. In macrophages, particularly in the artery wall, ABCA1 is thought to be important for the removal of a toxic pool of cholesterol, thereby preventing apoptosis.

2.1.1 Tangier Disease

Tangier disease is a rare autosomal disorder, thought originally to be recessive, but now accepted to be codominant, and is characterized by the almost complete absence of HDL. What little HDL is present is pre-*beta* HDL. CE accumulates in many tissues, notably the intestine and reticuloendothelial system, with the accumulation of orange-pigmented lipids in the tonsils and rectal mucosa. Peripheral neuropathies and a syringomyelia-like disorder accompany the disease, together with premature CAD. Fibroblasts cultured from affected patients showed very low efflux of cholesterol to acceptor apoA-I compared to normal cells. Efflux of cholesterol to HDL was little affected while that of phospholipid was greatly decreased. After numerous candidate genes were ruled out, linkage and subsequent studies confirmed that homozygous or compound heterozygous mutations in *ABCA1* underlie all cases of Tangier disease. Heterozygous *ABCA1* mutations account for some cases of primary hypoalphalipoproteinemia, though these are probably less than 10% of cases. The ABCA1 defects that cause Tangier disease appear to result primarily in impaired phospholipid efflux, which leads to secondary impairment of cholesterol efflux.

2.2 Caveolin

All cells actively acquire and efflux cholesterol to the retrieval pathway, to maintain homeostasis in plasma membranes. The process involves movement of cholesterol to the plasma membrane and is probably facilitated by the caveolin proteins coded by three caveolin genes, *CAV1, CAV2*, and *CAV3*. There are two isoforms of caveolin-1, *alpha* and *beta*, because there are two transcription start sites. The human *CAV1* and *CAV2* genes each have 3 exons and are located 18-kb apart at chromosome 7q31.2. The caveolin family of scaffold proteins, notably the 22-kDa caveolin-1, is found in caveolae, which are clathrin-free invaginations of the plasma membrane, rich in free cholesterol and sphingolipids.

Multiple caveolin molecules form highly ordered assemblies within caveolae. Concentrated in the caveolae are components of lipid signaling pathways, transmembrane receptor kinases, protein kinase C, protein kinase A, adenyl cyclase, and MAP signaling intermediates. In addition, the scavenger receptors SR-BI (SCARB1) and CD36 (SCARB3) are also located in caveolae. The caveolin polypeptides, which bind free cholesterol, are embedded in the plasma membrane with both the N- and C-termini in the cytoplasm. Short, approximately 20-residue, motifs in the caveolins bind to and recruit free cholesterol and proteins.

2.3 Lecithin Cholesterol Acyl Transferase

The enzyme LCAT rapidly esterifies the free cholesterol that is transferred to pre-*beta*-1 HDL from plasma membranes. The cholesteryl esters are transferred to HDL with *alpha* electrophoretic mobility. HDL are also acceptors of free cholesterol from other lipoproteins, notably LDL, and this transfer may be LCAT dependent.

The *LCAT* gene (chromosomal location 16q22.1) has six exons. Mature LCAT, secreted by the liver, is a 60-kDa, 416-residue glycoprotein with a hydrophilic C-terminus. There are regions with homology to apoE, LPL, and hepatic lipase (LIPC). Cofactor activation of LCAT has been attributed to apoA-I and apoA-IV.

A number of mutations causing LCAT deficiency have been reported, which result in decreased levels of HDL- and LDL-cholesterol esters. There is also abnormal architecture of virtually all lipoprotein species. These mutations are dispersed in various regions of LCAT, indicating that there are several important domains. Two mutations have been shown to cause cases of Fish-eye disease, which is associated with markedly reduced levels of HDL cholesterol. In one of these cases (T123I), the mutant protein has been shown to be capable of esterifying LDL cholesterol but not HDL cholesterol.

Studies using *in vitro* mutagenesis have shown that, of the four potential N-glycosylation sites, Asn84 is important for full enzymatic activity, though not for intracellular processing, and Asn272 is essential for secretion. The LCAT variant R158C appears to be a natural polymorphism.

2.4 Phospholipid Transfer Protein

Although the liver secretes nascent discoidal HDL, HDL particles are also formed in plasma, with the apolipoproteins and phospholipids being derived from triglyceride-rich lipoproteins (chylomicrons and VLDL). The supply of phospholipid for the formation of HDL particles is mediated by PLTP. Studies on transgenic animals have provided evidence that pre-*beta*-1HDL particles are generated by the activities of PLTP. PLTP-knockout mice have reduced levels of HDL, owing to decreased production and increased catabolism. As well as being important for pre-*beta*-1-HDL formation, PLTP plays an important role in remodeling larger HDL species, by converting smaller HDL_3 particles to larger HDL_2 particles. In addition to PLTP, hepatic lipase too can metabolize HDL_2 to particles of smaller diameter, and plays a role in pre-*beta*-HDL production.

While PLTP is expressed in many tissues, the source for most of the circulating protein is liver and adipose tissue. There is evidence that the *PLTP* gene is up-regulated at the transcriptional level by PPARα, LXR, and possibly by FXR. PLTP

is a highly glycosylated protein and has an apparent molecular mass of 81 kDa, with 476 amino acid residues. The human gene (13.3 kb) at chromosome 20q13.12 is composed of 16 exons and is organized in a manner similar to that of the gene for CETP. These two genes appear to have evolved from a common ancestor. PLTP has homology with (in addition to CETP) lipopolysaccharide-binding protein and neutrophil-bactericidal-permeability-increasing protein. PLTP is nonspecific in its transfer capabilities, being able to transfer most phospholipids in addition to diacylglycerol. It has also been shown to promote the exchange transfer of *alpha*-tocopherol (vitamin E) among lipoproteins.

2.5 Cholesteryl Ester Transfer Protein

CETP is responsible for the transfer of the cholesteryl esters formed by LCAT from HDL to the apoB-containing lipoproteins and facilitates the reverse transfer of triglycerides. The HDL triglycerides are subsequently hydrolyzed by hepatic lipase. CETP is an important factor in determining the ultimate size profile of LDL particles. It is a 70-kDa hydrophobic glycoprotein. Most of the circulating CETP is associated with the HDL fraction of plasma. The human gene, on chromosome 16q13, comprises 16 exons spanning 25 kb and codes for a 493-residue prepeptide. It is expressed in the liver, small intestine, adrenal glands, spleen, and adipose tissue. There is evidence for the presence of an alternatively spliced CETP mRNA species, lacking exon 9, in certain tissues and for only limited secretion of the corresponding protein.

Individuals with homozygous familial CETP deficiency have high levels of large, apoE-rich HDL particles and low levels of LDL cholesterol, but do not suffer from premature atherosclerosis. These subjects have markedly decreased catabolism of apoA-I and apoA-II. Two particular mutant alleles, D442G and a splicing defect in intron 14, account for 10% of the variance of HDL in the Japanese population. These alleles are relatively common, with heterozygosities of 7 and 2% respectively. Analysis of the CETP gene promoter revealed eight major haplotypes among Japanese subjects, with one being associated with lower CETP levels and higher HDL levels in plasma.

High-level expression of CETP in transgenic mice (a species in which plasma CETP is normally absent) is associated with an increased rate of catabolism of apoA-I. This leads to a decrease, both in the level of HDL cholesterol and in HDL particle size. These animals develop atherosclerosis more easily than control mice.

In addition to the transfer of HDL cholesterol esters by CETP to other lipoproteins and subsequent uptake by the liver, there are two other minor routes for cholesterol ester clearance. Firstly, apoE-rich HDL particles are endocytosed by hepatic receptors that recognize apoE, and secondly there is selective hepatic uptake of HDL cholesterol esters, but not apoA-I, by SR-BI, a process involving hepatic lipase.

2.6 Endothelial Lipase

Endothelial lipase (LIPG) is a recently recognized member of the lipase gene family, which includes lipoprotein lipase (LPL), hepatic lipase (LIPC), pancreatic lipase (PNLIP), phosphatidylserine-specific phospholipase A1 (PLA1A), and pancreatic lipase-related proteins 1 and 2 (PNLIPRP1 and PNLIPRP2). It has 44 and

41% homology with LPL and hepatic lipase, respectively. In particular, the active site catalytic triad, Ser169, Asp193 and His274, and heparin binding sites are conserved. A notable exception is the lid region responsible for substrate recognition. Unlike these two lipases it does not hydrolyze triglycerides; rather, its preferred substrate is phosphatidylcholine releasing the sn-1 acyl chain. It is expressed in a number of tissues, notably liver, thyroid, smooth muscle, bronchial epithelial cells, macrophages, and placenta. The human gene is at chromosome 18q21.1, and is 31 kb-long with 10 exons. The precise physiological function of endothelial lipase is not clear at present. However, evidence points to a role in HDL metabolism. Endothelial lipase knockout mice (*Lipg*−/−), and mice treated with an antiendothelial lipase antibody, had increased levels of HDL. The overexpression of this lipase in mice led to decreased HDL. Endothelial lipase hydrolyzes the main lipid constituent of HDL, phosphatidylcholine. It is not clear whether this occurs before or after binding of HDL to its receptor, SR-BI, that is, before or after much of the cholesterol content of the HDL particle has been transferred.

3
Cholesterol Metabolism

3.1
Synthesis

Cholesterol is required primarily to maintain the structure and characteristics of cellular membranes. It is also required as a precursor for steroid hormones and bile acids. Much of the cholesterol in cells is obtained from circulating LDL by uptake through the LDL receptor, and by a nonspecific pathway. However, most tissues, in particular, the liver, can synthesize cholesterol.

The isoprenoid biosynthetic pathway, of which cholesterol is the end product, can also supply cells with other compounds such as dolichol and ubiquinone. An isoprenoid intermediate in the cholesterol synthetic pathway, 15-carbon farnesyl pyrophosphate, and the related isoprenoid 20-carbon geranylgeranyl pyrophosphate, are used for the posttranslational prenylation of certain proteins (notably G proteins) at cysteine residues through thioether bonds. Prenylation, essential for membrane localization of a number of proteins, is catalyzed by several prenyltransferases. The gene products that are prenylated include many that are involved in signal transduction pathways. Examples are the ras, Rho, and Rab GTPases, Lamin A and B, and phosphorylase kinases. Cholesterol itself is covalently attached to the N-terminus of Shh, the product of the sonic hedgehog homolog gene (*SHH*) *via* a catalytic activity residing in the C-terminus. The Shh-cholesterol adduct is thereby restricted to zones within the developing cells in which Shh acts.

3.1.1 HMGCoA Synthase and Reductase

The initial precursor for cholesterogenesis is acetyl CoA. After conversion to acetoacetyl CoA, two key regulatory enzymes, hydroxymethylglutarylcoenzymeA (HMG-CoA) synthase and HMG-CoA reductase are responsible, sequentially, for the formation of mevalonic acid. This is the substrate for the formation, *via* geranyl pyrophosphate and farnesyl pyrophosphate, of squalene. Cyclization of squalene produces the first sterol, lanosterol. This is modified further by a series of enzymes forming cholesterol. The enzymatic reduction of

HMG-CoA to mevalonic acid, which utilizes 2 molecules of NADPH, represents the first and rate-determining step in isoprenoid and cholesterol biosynthesis.

The genes for HMG-CoA synthase, HMG-CoA reductase, farnesyl pyrophosphate synthase, squalene synthase (all regulatory enzymes), and the LDL receptor are coordinately regulated by the amount of cholesterol available to the cell. As well as having unique enhancers, they share common cis-acting sterol regulatory elements (SREs) in their promoters.

The gene for HMG-CoA synthase (HMGCS1) on chromosome 5p12 spans 23 kb and has 9 exons, and the gene for HMG-CoA reductase (HMGCR) on chromosome 5q13.3 spans 24 kb and has 19 exons. Seven membrane-spanning segments, in the 339-residue N-terminus, that anchor the 97-kDa HMG-CoA reductase protein to the smooth ER, act as a sterol-sensing domain, which controls the regulation of enzyme degradation. The catalytic site is located in the 548-residue C-terminus, which projects into the cytosol.

Regulation of both enzymes is *via* negative feedback control by sterol and nonsterol products of mevalonic acid. In addition to transcriptional and translational regulation, HMG-CoA reductase is regulated posttranslationally by phosphorylation of the catalytic domain with AMP-activated protein kinase. This latter mode of cross regulation, which is independent of the feedback control, coordinates isoprenoid synthesis with cellular energy balance.

Several inhibitors of HMG-CoA reductase, namely, the statin class of drugs, cause hepatic induction of LDL receptor expression. This leads to increased clearance of VLDL remnants and LDL, which results in a highly effective lowering of plasma levels of LDL cholesterol. What seemed to be evidence for the existence of an additional gene, coding for a second HMG-CoA reductase isoform expressed in peroxisomes, has been discounted. It is now thought to be merely the result of alternative targeting of the ER enzyme.

3.1.2 Smith–Lemli–Opitz Syndrome

First described in 1964, Smith–Lemli–Opitz Syndrome (SLOS) is a rare developmental disorder characterized by high levels of 7-dehydrocholesterol and low levels of cholesterol in plasma. It is caused by a defect in the gene for the cholesterol biosynthetic pathway enzyme, 7-dehydrocholesterol reductase (DHCR7). This enzyme has a TM sterol-sensing domain similar to that found in HMG-CoA reductase, SREBP cleavage activation protein (SCAP), the Niemann–Pick type C1 protein (NPC-1) and Patched (the Shh receptor). Patients have multiple congenital malformations that vary in clinical severity. The lack of sufficient cholesterol interferes with Shh signaling which is crucial for normal embryogenesis. Congenital disorders less common than SLOS, affecting other sterol modification enzymes, have also been reported.

3.1.3 Acyl CoA: Cholesterol Acyltransferases

Acyl-CoA: cholesterol acyltransferase (ACAT) catalyzes the long-chain fatty acyl esterification of cholesterol and is crucial for the regulation of the level of free cholesterol within cells. Cholesterol esters are used for chylomicron and VLDL production. In steroidogenic tissues, such as the adrenal gland, stored CE is used as the precursor for steroid hormone. Free cholesterol released after uptake of LDL is esterified by ACAT and stored in cytoplasmic lipid droplets. This process is important in the macrophages and smooth

muscle cells of the artery wall where it can lead to the formation of CE-loaded foam cells, features of early atherosclerotic lesions. ACAT activity in liver is regulated by the availability of unesterified cholesterol. Hepatic ACAT activity helps to maintain the free cholesterol concentration within the liver and plays a role in regulating the secretion of cholesterol, as a constituent of VLDL, into plasma. Hence, ACAT is involved in the regulation of apoB secretion from the liver. It also plays a role in regulating the efflux of free cholesterol into bile. ACAT activity in the liver is decreased in patients with cholesterol gallstones, and this decrease contributes to the increased availability of free cholesterol for bile secretion.

ACAT is a membrane-bound protein of the endoplasmic reticulum, which initially proved difficult to purify to homogeneity. Two human genes with ACAT activity have been identified. Because the gene for acetoacetyl-CoA thiolase has been given the symbol ACAT, the acyl-CoA: cholesterol acyltransferases have been renamed as *sterol O-acyltransferases*, SOAT1 and SOAT2. The *SOAT1* gene is on chromosome 1q25.2, spans 61 kb, has 16 exons, and codes for a 550-residue protein. SOAT2 is on chromosome 12q13.13, spans 21 kb, has 15 exons, and codes for a 522-residue protein. SOAT2 (ACAT2) was discovered on the basis of high homology with SOAT1 from codon 102 to the C-terminus. The rare phenomenon of trans-splicing appears to be the origin of a minor 4.3 kb ACAT1 mRNA, which has an additional exon from chromosome 7.

There has been confusion regarding the sites of expression of these two genes. *ACAT1* is more widely expressed than *ACAT2*, which is mainly expressed in small intestine at the apical region of the villi and in liver. In humans, ACAT1 activity dominates that of ACAT2 in human liver. However, in ACAT1 knockout mice hepatic CE levels and synthetic rates were normal. The only tissues affected were the adrenals and macrophages. ACAT2 disruption in mice resulted in very low ACAT enzyme activity in liver and intestine. These animals showed resistance to diet-induced hypercholesterolemia and to the formation of cholesterol gallstones because of the decreased intestinal cholesterol absorption. Whatever the relative expression levels of ACAT1 and ACAT2 are in human liver, they are probably different from those in mouse liver.

Both enzymes are membrane bound, each with five TM domains, being found in microsomal cell fractions. It has been proposed that CE that is formed within the ER bilayer by ACAT is processed in one of two possible ways. It can either be directed as lipid droplets into the cytosol or, in cells producing lipoproteins, transferred to apoB in the ER lumen by MTP.

3.2 Catabolism: Bile Acid Metabolism and Disorders

The main bile acids, taurine or glycine conjugates of cholic, deoxycholic, and chenodeoxycholic acids, are synthesized from cholesterol in the liver. This is the primary means by which cholesterol is catabolized, the hepato-biliary system being the main pathway for cholesterol excretion. The first, rate-controlling step of the major pathway of bile acid synthesis, is the formation of 7α-hydroxycholesterol. This is catalyzed by cholesterol 7α-hydroxylase (CYP7A1), a liver-specific, cytochrome P-450-dependent, mixed function oxidase. In humans, the pathway leads to two

primary bile acids, cholic acid and chenodeoxycholic acid.

CYP7A1, located in the smooth ER, is subject to feedback regulation at the transcriptional level, with mRNA levels decreased by high levels of bile acids and positively correlated with the availability of cholesterol. *CYP7A1* gene transcription is subject to feedback regulation by bile acids through a bile acid response element (BARE), and is positively correlated with the availability of free cholesterol. CYP7A1 mRNA levels are regulated by thyroid hormone and insulin. There have been numerous studies on the regulation of CYP7A1, and the promoter region has been extensively analyzed. However, there remain a number of unresolved questions, especially with regard to the human gene, and a number of contradictions exist among the studies. It has been emphasized that there are important differences in the types of bile acids among species and the response of CYP7A1 to high-cholesterol diets, especially between humans and widely studied rodents. Nevertheless, there is a current, commonly accepted, model that attempts to explain the regulation of CYP7A1 and bile acid homeostasis, albeit based on rodent data.

The concentration of oxysterols, which are activating ligands for the nuclear receptor LXR-α (NR1H3), is thought to reflect the level of cell cholesterol. High levels of cholesterol, and hence of oxysterols, increase the transcription of CYP7A1, basal transcription being the result of the binding of CPF (or LRH-1, the mouse homolog) encoded by the *NR5A2* gene, and of HNF4-α, to the promoter. There is evidence that HNF-1 binds to and activates the CYP7A1 promoter in humans but not in the rat. A number of bile acids, notably chenodeoxycholic acid (CDCA), are activating ligands for the nuclear receptor FXR (NR1H4). FXR (see Sect. 5.4) is an orphan nuclear hormone receptor expressed within hepatocytes and enterocytes in the terminal ileum. It is thought that FXR regulates CYP7A1 indirectly because no consensus binding site has been identified in the promoter. FXR upregulates the gene for SHP (small heterodimer partner), and the SHP protein binds to and inhibits the activation of CPF (LRH-1) and HNF4-alpha. This model holds up better in rodents than in humans. Unlike its action on the rat cyp7a1 promoter, LXR has only a small effect on the human promoter to which it binds only weakly. It has been reported that FXR only modestly increases SHP transcription in human HepG2 cells. SREBP can activate the human SHP promoter, but not that of the mouse gene. The transcriptional coactivator PGC-1α activates *CYP7A1* gene transcription. *CYP7A1* is repressed by the c-Jun N-terminal kinase pathway, a process that involves fibroblast growth factor 19 (FGF-19), which is regulated by FXR.

The human gene for cholesterol 7α-hydroxylase, which is 10-kb long, lies at chromosome 8q12.1, contains 6 exons, and codes for a 504-residue peptide, which contains sterol and heme binding sites. Overexpression of the gene in hamsters caused a large decline in LDL, and transgenic mice had resistance to diet-induced gallstone formation and to atherosclerosis. There have been conflicting reports as regards the effect on lipid levels in plasma, and the phenotype in general, in knockout mice. In one colony, most homozygous animals died within 18 days of birth unless mothers were supplemented with vitamins and cholic acid was added to the diet. There were no changes in serum lipid levels. The phenotype consisted of fat malabsorption, abnormal lipid excretion, and skin and behavioral abnormalities. A second colony

survived on an unsupplemented diet, had elevated serum cholesterol, and had a proatherogenic phenotype. CYP7A1 polymorphisms, notably an SNP at −204 in the promoter, have been associated with differences in LDL-cholesterol levels. Screening of hypercholesterolemic patients, using a differential DNA melting technique, revealed several rare CYP7A1 variants.

Cholesterol 7α-hydroxylase initiates the classical or neutral bile acid synthesis pathway. An additional pathway, the alternative or acidic pathway, does not involve CYP7A1 and is initiated by mitochondrial sterol 27-hydroxylase (CYP27A1). Subsequently, a microsomal enzyme, oxysterol 7α-hydroxylase (CY7B1), introduces a 7α-hydroxyl group. The rest of the pathway is similar to the neutral pathway. However, chenodeoxycholic acid is the main product here, and not cholic acid.

3.2.1 Cholesterol 7α-hydroxylase Deficiency

A number of CYP7A1 coding region variants have been found, one of which is a frameshift mutation (L413fsX414) that results in loss of catalytic activity due to deletion of the heme binding domain of the enzyme, and leads to the disorder *cholesterol 7α-hydroxylase deficiency*. Two homozygous males had highly reduced bile acid excretion, significant hypercholesterolemia and hypertriglyceridemia, and were profoundly resistant to treatment by HMG-CoA reductase inhibitors (statins). They both had early gallstone disease. Liver biopsy and stool bile acid analysis indicated limited upregulation of the alternative bile acid synthetic pathway. The observed doubling of liver cholesterol content, due to low conversion to bile acids, may have resulted in downregulation of hepatic LDL receptors that could account for the raised plasma cholesterol. In terms of the hypercholesterolemia, there appears to be a gene dosage effect, with heterozygotes also affected. Thus, cholesterol 7α-hydroxylase deficiency is an autosomal codominant disorder.

3.2.2 Oxysterol 7α-Hydroxylase Deficiency

A single case of this disorder, associated with lack of synthesis of primary bile acids, was reported in a human infant due to a nonsense mutation in exon 5 of the *CYP7B1* gene. The child had cholestasis and early liver failure, due to accumulation of toxic monhydroxycholenoic acids. CYP7A1 activity was low in this patient, as in normal infants, and therefore was not able to compensate for the absence of CYP7B1. In contrast, *Cyp7b1* knockout mice had normal bile acid metabolism, with plasma cholesterol and triglycerides unchanged.

3.2.3 Cerebrotendinous Xanthomatosis

First reported in 1937, cerebrotendinous xanthomatosis (CTX) is caused by a deficiency of sterol 27-hydroxylase (CYP27A1). It is characterized by a marked reduction in bile acid synthesis, an accumulation of cholesterol and cholestanol in many tissues, and by ataxia, dementia, and premature atherosclerosis. Cyp27a1 knockout mice had even lower bile acid production, were hypertriglyceridemia, but had no CTX-like symptoms.

3.3 Disorders of Intracellular Lipoprotein Degradation

3.3.1 Wolman Disease and Cholesteryl-ester Storage Disease

Degradation of lipoproteins following their uptake by tissues involves lysosomal acid lipase, which catalyzes the hydrolysis of

cholesteryl esters and triglycerides. A deficiency in the activity of this enzyme can leads to two disorders, Wolman disease, and cholesteryl ester storage disease (CESD). Both are autosomal recessive disorders caused by mutations in the gene for lysosomal acid lipase (LIPA) on chromosome 10q23.31. The gene has 12 exons and spans 201 kb. Transcription leads, by alternative splicing, to two mRNAs that code for 399- and 401-residue proteins, respectively. Wolman disease is a severe disorder invariably fatal in the first year of life. It is associated with a failure to thrive, multiple gastrointestinal symptoms, including steatorrhea and hepatosplenomegaly, and adrenal calcification. CESD is associated with hepatomegaly, but its symptoms are generally less severe. It sometimes does not manifest in childhood. Owing to hyperlipidemia, severe premature atherosclerosis is common.

3.3.2 Niemann–Pick Disease Type C

Caused by defects in at least two genes, Niemann–Pick Disease Type C, first described in 1958, is a rare autosomal recessive disorder characterized by aberrant intracellular trafficking of endocytosed LDL cholesterol. The cholesterol accumulates in lysosomes. It is often a fatal disease with progressive visceral and neurological symptoms. The human *NPC1* gene spans 55 kb on chromosome 18q11.2 with 25 exons, and encodes a 1278-residue integral membrane protein with a sterol-sensing domain similar to HMG-CoA reductase, SCAP and Patched. The second gene associated with the disorder, NPC2, is on chromosome 14q24.3, spans 13 kb, and codes for a 151-residue protein. This has a lipid-binding motif and functions, together with the NPC1 protein, to facilitate cholesterol transport in the late lysosomal/endosomal pathway.

A gene related to *NPC1* is *NPC1L1* (Niemann–Pick disease, type C1, gene-like 1). The NPC1L1 protein product, highly expressed in enterocyte brush border membranes, plays a poorly understood, but critical, role in the intestinal absorption of cholesterol. It functions in the pathway of cholesterol absorption in which the cholesterol-lowering drug ezetimibe acts. Ezetimibe failed to inhibit the uptake of cholesterol in NPC1L1 knockout mice.

4 Triglyceride and Phospholipid Metabolism

Many triglyceride and phospholipid pathway enzymes are intimately bound to membranes and have proved difficult to purify, sequence, and clone. The steps leading to the formation of diacylglycerol from acyl CoA, *via* phosphatidate, are common to both the triglyceride and phospholipid pathways. Diacylglycerol is synthesized *via* the action of phosphatidic acid phosphatase (PAP). There is a family of PAP enzymes encoded by three genes, *PPAP2A, PPAP2B*, and *PPAP2C*. In each case, isoforms resulting from alternative splicing exist. They have an N-glycosylation site and 6 TM domains, being integral membrane glycoproteins. The PAPs also function in phospholipase D signal transduction.

The last step in the synthesis of phosphatidyl choline, the major phospholipid, is formed by the action of CDP-choline: 1,2-diacylglycerol choline phosphotransferase (or choline/ethanolaminephosphotransferase) an intrinsic, ER and Golgi enzyme. The human gene *CEPT1* located on chromosome 1p13.2 has 9 exons, spans 45 kb, and encodes a 396-residue protein. CEPT also catalyses the formation of phosphatidylethanolamine. First cloned from

yeast, the protein has a molecular mass of 46 kDa and seven membrane-spanning helices. CDP-choline itself is formed by the action of CTP:phosphocholine cytidyltransferase (CT). Rat CT has been cloned and has a molecular mass of 42 kDa. It lacks a hydrophobic domain and is attached to membranes by a 58-residue amphipathic α-helix. There are two human CT genes: *PCYT1A* and *PCYT1B*.

In humans, there are two enzymes that catalyze the final step in triglyceride synthesis. The diacylglycerol acyltransferases DGAT1 and DGAT2 utilize fatty acyl-CoA and diacylglycerol as substrates to form triglyceride. The *DGAT1* gene, first recognized because of its homology to ACAT, is at chromosome 8q24.3, has 17 exons, and spans 11 kb. *DGAT2* on chromosome 11q13.3 has 8 exons spanning 33 kb. It is expressed widely, but at high levels in liver and white adipose tissue.

5
Role of Nuclear Hormone Receptors

5.1
Sterol Regulatory Element Binding Proteins

The 5′ flanking region of the LDL receptor (LDLR) gene was found to contain a sterol regulatory element (SRE). In the presence of sterols, this element loses its ability to synergistically enhance transcription *via* two direct repeats that bind to the Sp1 transcription factor. A nuclear protein was identified that binds to the SRE and is termed *sterol regulatory element binding protein* (SREBP). SREs have since been identified in the promoters of other genes involved in sterol and fatty acid synthesis. Three similar transcription factors, SREBP-1a, SREBP-1c, and SREBP-2, all of which are 120-kDa proteins, have been identified, and they all bind to SREs. SREBP-1a, and SREBP-1c differ as a result of separate transcription starts sites in the *SREBF1* gene involving alternative initial exons (human gene: chromosome 17p11.2). The SREBP-2 protein is encoded by the *SREBF2* gene (human gene: chromosome 22q13.2). In mammals, SREBP-1a and SREBP1-c primarily activate the genes of fatty acid synthesis, and SREBP-2 activates those of sterol synthesis. The SREBPs are basic helix–loop–helix leucine zipper (bHLH-zip) transcription factors found in a wide variety of animals. The precursor peptides are attached to the ER membrane with the N-terminal bHLH-zip domain and the C-terminal regulatory domain located in the cytoplasm. The presence of sterols blocks a two-step proteolytic cleavage of SREBP that occurs in sterol-depleted cells when a released N-terminal fragment of the protein enters the nucleus and activates transcription of sterol-regulated genes *via* the SREs. In the presence of sterols, SREBP is bound by its regulatory domain to the SREBP-cleavage-activating protein (SCAP). SCAP has eight membrane-spanning helices in its N-terminus and a C-terminal propeller region composed of multiple WD repeats that binds to SREBP. The SREBP–SCAP complex is retained in the ER by proteins that interact with the sterol-sensing domains of SCAP, and which are encoded by insulin-induced genes 1 and 2 (*INSIG-1* and *INSIG-2*). Other proteins, not yet identified, are thought to retain the Insig proteins in the ER since they do not possess ER retention signals. In the absence of sterols the Insig proteins release SREBP–SCAP, which migrates in COPII (coat protein complex) vesicles to the Golgi apparatus. Here, the initial cleavage of SREBP by *site 1 protease (S1P)* (also called

PCSK8), encoded by the *MBTPS1* gene, occurs in a protein loop in the lumen of the ER. A second cleavage by the metalloproteinase S2P, encoded by the *MBTPS2* gene at site 2 in a transmembrane domain, releases the N-terminal active peptide.

5.2 Peroxisome Proliferator-activated Receptors

The peroxisome proliferator-activated receptor (PPAR) family of transcription factors was discovered in rodents. In rodents, PPARs are activated by chemicals, resulting in larger and more numerous peroxisomes. This is accompanied by increased β-oxidation through activation of the acyl CoA oxidase gene, which contains, in its promoter, a peroxisome proliferator response element (PPRE) consisting of a direct repeat of the motif PuGGTCA, to which PPAR binds as a heterodimer with the 9-cis retinoic receptor (RXR, NR2B1). PPARs play roles in differentiation, cell division, apoptosis, and inflammation. They are also key regulators of lipid and lipoprotein metabolism and of the pathways of gluconeogenesis and glycolysis. There are three human *PPAR* genes, *PPARA* (chromosome 22q13.31), *PPARG* (chromosome 3p25.2), and *PPARD* (chromosome 6p21.31) that encode, respectively, PPARα, PPARγ, and PPARδ. The first, PPARα is expressed at high levels in liver, kidney, muscle, and heart where it activates fatty acid β-oxidation. The second, PPARγ, in contrast, is highly expressed in intestine, adipose, and mammary tissue. It promotes the storage of lipids. The third receptor, PPARδ is more widely expressed than the other two members of the family. There are a number of fatty acid and fatty acid–derived compounds that are ligands for PPARs. In particular, a hydroxyeicosatetraenoic acid (HETE) derivative 8S-HETE and leukotriene B4 are potent activators of PPARα. Natural ligands for PPARγ include prostaglandin J2, 15-HETE and the hydroxyoctadecadienoic acids (HODE) 9-HODE and 13-HODE. The hypolipidemic fibrate drugs and antidiabetic glitazone drugs are synthetic PPAR activators.

5.3 Liver X Receptors

The orphan nuclear receptors LXRα and LXRβ are activated by oxysterols, though the nature of the precise physiological ligand is still unclear. Examples of natural compounds known to activate LXR are 24(S),25-epoxycholesterol and 20(S)-, 22(R)-, 24(S)-, and 27-hydroxycholesterol. The LXRs are key regulators of numerous genes involved in lipid and carbohydrate metabolism, the inflammatory response, and energy homeostasis. They bind as heterodimers with RXR to DR-4 (or LXRE) response elements in the promoters of target genes. These are two hexanucleotide repeats with the consensus (T/A/G)G(G/T)(G/T)(T/C)A, separated by four nucleotides. Lipid transfer and transporter genes that are targets for LXRs include *ABCA1*, *ABCG1*, *ABCG4*, *ABCG5/G8*, *CETP*, and *PLTP*. Gene targets involved in fatty acid synthesis are, *ACC* (acetyl CoA carboxylase), *FAS* (fatty acid synthase), and *SCD* (stearoyl CoA desaturase). Two apolipoprotein genes, *APOC2* and *APOE*, are also upregulated by LXRs as is *SREBP-1c* and *LPL*. The *Cyp7a1* gene in rodents, but not in humans is a target for LXRs. The *LXR* genes themselves are subject to positive feedback autoregulation by LXRs. The human gene for LXRα (*NR1H3*, chromosome 11p11.2) is expressed at high levels in

the liver, kidney, adipose tissue, and intestine, whereas that for LXRβ (*NR1H2*, chromosome 19q13.33) is more ubiquitously expressed. In liver, LXRα is induced by insulin, leading to upregulation of lipogenesis and downregulation of gluconeogenesis *via* repression of the rate-limiting enzyme phosphoenolpyruvate carboxykinase gene (*PCK1*).

5.4 Farnesoid X Receptor and Pregnane X Receptor

At high concentrations, farnesol was found to activate an orphan nuclear receptor. Thus, this receptor was named FXR (farnesoid X receptor). Since then FXR (human gene, *NR1H4*, chromosome 12q23.1) has been shown to be a bile acid sensor with the highest activation by chenodeoxycholic acid. Some 25- and 26-hydroxylated bile acid intermediates also have high affinity for FXR. With RXR, it binds as a heterodimer to the bile acid response elements (BARE) of a number of genes involved in bile acid and lipid metabolism. Target genes upregulated by FXR include *ABCC2* (multidrug resistance protein: MRP2), *ABCB11* (canalicular bile salt export pump: BSEP), *FABP6* (fatty acid–binding protein 6, the ileal bile acid-binding protein), *SHP* (see Sect. 3.2 above), *ApoC-II*, and *PLTP*.

A related nuclear receptor, the pregnane X receptor, PXR (human gene, *NR1I2*, chromosome 3q13.33), also binds as a heterodimer with RXR. Natural ligands include lithocholic acid. It activates several cytochrome P450 enzyme genes, notably the cluster of four *CYP3A* family genes, *CYP2B*, *ABCB1 (MDR1)* and *ABCC2 (MRP2*). These enzymes are involved in drug metabolism, and some of them in lipid synthesis and transport also.

6 The Apolipoproteins

6.1 The Apolipoprotein Multigene Family

Nine apolipoproteins, all of which are exchangeable among lipoproteins, are members of a multigene family. These are *apoA-I*, *apoA-II*, *apoA-IV*, *apoA-V*, *apoC-I*, *apoC-II*, *apoC-III*, *apoC-IV* and *apoE*. The genes have a similar structure and have evolved from a common ancestor that was similar to apoC-I. Each has 4 exons, except apoA-IV, and apoA-V in which exons 1 and 2 have fused. Within exon 3 there is, in each case, a conserved region of 33 codons. This amphipathic α-helical lipid binding domain is a trimer of 11 amino acids. The fourth exon of each codes for variable numbers of consensus, 22-residue and, in some cases, 11-residue, lipid-binding tandem repeats.

The *apoA-I*, *apoC-III*, *apoA-IV* and *apoA-V* genes (Table 2) are clustered in a 48-kb region on chromosome 11 (11q23.3). This cluster is regulated by an enhancer region, necessary for intestinal expression of apoA-I and apoA-III, upstream of the *apoA-III* gene. Transcription factors involved include SP1 and HNF4. In a patient with premature atherosclerosis, a 6-kb inversion affecting the *apoA-I* and *apoC-III* genes resulted in apoA-I and apoC-III deficiency. In another case the entire gene cluster was deleted, resulting in apoA-I, apoC-III and apoA-IV deficiency and very low HDL levels. Population studies using polymorphic markers suggest an association between the A-I/C-III/A-IV/A-V locus and the frequency of hyperlipidemia and atherosclerosis. A case-control study of SNPs at this locus showed significant association between the FCH phenotype and the *ApoA-I* and *ApoA-V* genes.

Tab. 2 The human apolipoprotein genes.

Apo(a)[a]	lipoprotein Lp(a)	LPA	6q26–27	212	39	4548	550	variable[a]	Lp(a)

[a]Data for apo(a) is given for the gene in the public domain genome sequence. The protein size can vary from 300 to 800 kDa. The concentration in human plasma can vary from undetectable to over several hundred mg dL^{-1}.

The genes for apoC-I, apoC-II, apoC-IV, apoE, (Table 2) and an apoC-I pseudogene are clustered on chromosome 19 (19q13.32) spanning 44 kb. The regulation of this cluster is discussed below (Sect. 6.11).

6.2 Apolipoprotein A-I

The major protein component of HDL, apoA-I is an activator of LCAT. The secreted 249-residue propeptide is processed in the plasma to the mature 243-residue (28 kDa) form. A number of rare charge variants have been detected by isoelectric focusing. Two of these, P165R and R173C (apoA-I Milano), in addition to a number of truncated variants, are associated with low levels of HDL. In the case of apoA-I Milano, the decrease in the level of HDL is due to an elevated rate of catabolism of the abnormal apoA-I species. Recently, clinical trials of intravenously infused recombinant apoA-I Milano have shown regression of coronary atherosclerosis. The practicality of this approach *versus* more conventional drug therapy in treating large numbers of patients is questionable. Several mutations, including G26R and L60R, cause amyloidosis. Two others, K107del and P165R, are mildly defective in activating LCAT.

An XmnI RFLP in the 5′flanking region is associated with hypertriglyceridemia in some populations. A possible functional single-base G/A substitution polymorphism in the promoter at nucleotide −75, in one of two inverted repeats, was associated with differences in HDL levels in some populations.

A number of cis-acting elements upstream of the gene have been identified as required for full liver-specific expression of apoA-I. However, while only 256-bp 5′ of the *apoA-I* gene are required for hepatic expression, a construct containing 5.5-kb 5′ and 4-kb 3′ of the human gene was not sufficient for intestinal expression in transgenic mice. This was achieved only when a construct was used that contained both the *apoA-I* and *apoC-III* genes together with 300-bp 5′ to the *apoA-I* gene and 1.4-kb 5′ to the *apoC-III* gene.

ApoA-I production and the level of the mRNA in rat liver are stimulated by thyroid hormone, an effect due both to increased transcription and to stabilization of apoA-I nuclear RNA. HNF-4, a member of the thyroid/steroid hormone receptor superfamily, has been shown to interact with a sequence in the 5′ flanking region and to increase promoter activity. Inhibitory effects have been shown for another DNA-binding protein, ARP-1, at the same site.

The overexpression of human apoA-I in transgenic mice increased the HDL cholesterol levels and prevented early diet-induced atherosclerosis. When these animals were crossed with apoE-deficient mice there was a marked decrease in the development of atherosclerosis, which is a characteristic of the apoE-deficient animals.

Homozygous apoA-I-deficient mice produced by gene targeting had only 20% of the normal level of HDL cholesterol but were generally healthy.

6.3 Apolipoprotein A-II

A secondary protein component of HDL, apoA-II is synthesized and secreted mainly by the liver and intestine. Unlike apoA-I it does not activate LCAT. Like apoA-I, it is regulated both transcriptionally and translationally.

Following cleavage of the 18-residue signal sequence some of the 82-residue

propeptide is cleaved prior to secretion, forming the mature 77-residue peptide. The rest is processed in the plasma. ApoA-II contains one free cysteine residue, enabling it to form heterodimers with apoE and apoD, though most of it exists in the form of a homodimer. The physiological function of apoA-II is largely unknown. It may be involved in the modulation of LCAT and HTGL activity.

Numerous studies have explored the regulation of the human gene expression. A diverse set of promoter elements have been identified. An MspI polymorphism at the 3′ end of the gene, in an Alu repeat sequence, has been reported to be associated with differences in the levels of apoA-I and apoA-II in serum.

An increased tendency to develop atherosclerotic lesions was seen in transgenic mice that overexpress human apoA-II. These animals had elevated levels of HDL and the particles were larger with a higher ratio of apoA-II to apoA-I when compared with normal mice.

6.4
Apolipoprotein A-IV

The 46-kDa glycoprotein, ApoA-IV is synthesized mainly in the small intestine and exists in a number of isoforms. The precise role of apoA-IV is unknown, but, like apoA-I, it activates LCAT and may be involved in reverse cholesterol transport. It has been reported to be a satiety factor. ApoA-IV is rapidly catabolized, having a tenfold higher fractional catabolic rate than apoA-I. The rate of synthesis determines the level of apoA-IV in plasma.

Three common polymorphisms exist: N127S, T347S and Q360H. With the latter polymorphism, the fractional catabolic rate of the *His* allele product has been reported to be lower than that of the more common *Gln* allele (frequency 92%). Genotypic variation in the *APOA-1V* gene affects the response of LDL cholesterol to diet.

6.5
Apolipoprotein A-V

Unlike the other apolipoproteins, apoA-V (and apoC-IV) was not discovered first as a protein isolated from plasma. Rather, the presence of apoA-V was revealed in the rat as the most highly upregulated of several novel genes following partial hepatectomy, and as a result of a comparison of the mouse and human genomes. It shows noticeable homology with apoA-I and apoA-IV, and the gene lies close to the cluster on chromosome 11q23 together with the genes for these two apolipoproteins as well as apoC-III. The apoA-V protein was then identified in plasma in the HDL fraction. Overexpression, either as a transgene, or by adenovirus transfection, resulted in decreased levels of plasma triglycerides. In contrast, knockout mice showed a marked increase in triglycerides. Together with the confirmation that functional FXR and PPARα response elements exist in the promoter for apoA-V, this strongly suggests a role in the regulation of triglyceride metabolism in the liver. The upregulation of apoA-V after hepatectomy suggests it has a role in the provision and trafficking of lipid for formation of new cell membranes. The apoA-V sequence contains amphipathic α-helices with an overall 60% α-helical content. Like ApoA-I, it can organize dimyristoylphosphatidylcholine vesicles into discoidal structures with diameters of 15 to 20 nm. However, unlike ApoA-I, it only poorly activates LCAT and does not increase cholesterol efflux from cAMP-stimulated macrophages.

6.6 Apolipoprotein B

In plasma from fasting humans, 90% of circulating apoB is in LDL, 8% in IDL and 2% in VLDL and chylomicrons. A centile nomenclature is used to describe apoB species based on their molecular weights. There are two circulating forms, apoB-48 and apoB-100 (Table 2). C-terminally truncated apoB-48, found on chylomicrons and their remnants, is produced in humans in the intestine. ApoB mRNA (14 kb in length) is edited by an editing complex in the nucleus of intestinal enterocytes in an enzyme-mediated process, such that codon 2153 becomes UAA (a stop codon) in place of CAA (Glu) in the gene sequence. A 26-nucleotide domain, 6662 to 6687, is highly conserved in mammals and necessary for editing to occur. The editing enzyme, Apobec-1, a 27-kDa protein with cytidine deaminase activity, was isolated and cloned from rat intestine. Additional factors are required for the editing to occur. The first to be identified is the Apobec-1 complementation factor (ACF), a 65-kDa protein.

In humans, the liver makes only the apoB-100 found in plasma on VLDL, IDL, and LDL. ApoB mRNA editing is undetectable in liver from humans, pigs, cows, sheep, cats, and monkeys. In liver from rabbits and guinea pigs, editing activity is very low. However, in several species, including dogs, horses, rats, and mice, an appreciable degree of editing has been found. The extent of this hepatic editing may be an important determinant of the level of apoB-containing lipoproteins in the circulation.

There is little acute metabolic regulation of hepatic levels of apoB mRNA. The availability of lipid and the extent of intracellular degradation of apoB are important in regulating secretion rates. The proteasome–ubiquitin pathway is the major means for the degradation of the apoB that fails to be lipidated.

Much larger than the exchangeable apolipoproteins, apoB has a globular N-terminus followed by four alternating amphipathic α-helical and β-sheet domains. This ''pentapartite'' structure is given as NH_2-$\beta\alpha$1-β1-α2-β2-α3-CO_2H. Through interaction with MTP, the $\beta\alpha$1 domain forms a lipid pocket that promotes lipid accumulation in the early stages of VLDL formation. The β1 and β2 hydrophobic surfaces interact with, and organize, the lipoprotein lipid core. The overall structure of native LDL is generally thought to be spherical. ApoB is highly glycosylated *via* 16 N-linked sites, with carbohydrate contributing 35 kDa of the molecular weight of apoB-100. Two regions (residues 1280 to 1320 and 3180 to 3282) are particularly sensitive to cleavage by endoproteases, an indication that they are exposed on the surface of LDL. Thrombin cuts at 1297 and 3249, forming three fragments, T4 (N-terminal), T3 (central) and T2 (C-terminal). The region from residues 3000 to 3600 that flanks the T2/T3 junction contains sequences responsible for binding to the LDL receptor. Receptor-blocking monoclonal antibodies have been mapped to this region. Two positively charged sequences in this region (residues 3147 to 3157 and 3359 to 3367) bind strongly to heparin. The second of these has close homology to the LDL receptor binding domain of apoE.

The tissue-specific regulation of expression of the *apoB* gene is complex with many cis- and trans-acting factors. Regulation of intestinal expression remains largely enigmatic. Studies with transfected cells, *in vitro*, and with transgenic mice have provided an understanding of the
